Abstract

Geological structures occur on a vast range of scales in Earth's lithosphere. Because Earth's lithosphere is rheologically heterogeneous, a multiscale approach is necessary to relate these structures to the tectonic history of orogens. One such approach, called the multi-order power-law approach (MOPLA), has been developed recently. In this study, MOPLA is applied to the Shangdan tectonic zone (SDTZ) in the Qinling orogenic belt (QOB). The kinematics of the SDTZ and its relation to the country rock deformation are crucial questions for Qinling tectonics, having both been the subject of debate for decades. Detailed work is conducted along the SDTZ to address these two fundamental questions.

MOPLA treats a heterogeneous material as a continuum of rheologically distinct elements. The rheological properties of the material and the mechanical fields of the constituent elements are computed by solving the partitioning and homogenization equations self-consistently. The computation is based heavily on the numerical evaluation of Eshelby tensors. This thesis develops an optimal scheme for evaluating Eshelby tensors and implements the scheme in MATLAB to improve the computational efficiency of MOPLA.

Multiscale structural analysis is performed along the SDTZ. Three deformation events are identified in the SDTZ and its adjacent areas. D_1 deformation is a NE-SW shortening deformation and occurred between ca.385-355Ma. D_1 deformation is only observed to the north of the SDTZ in western Qinling. D_2 deformation is a strike-slip dominant deformation and occurred between ca.227-201Ma. In western Qinling, D_2

deformation is a dextral strike-slip along the SDTZ. In eastern Qinling, D₂ deformation is a sinistral strike-slip along the SDTZ and N-S shortening deformation in the Liuling Group that is south of the SDTZ. D₃ deformation is an along-orogen extension and occurred between ca.140-135Ma. D₃ deformation is only observed in the Liuling Group in eastern Qinling. D₂ deformation, the opposite shearing along the SDTZ and the N-S shortening deformation in the Liuling Group, was a response to the oblique convergence between the South China Block and the North China Block. The convergence angle is constrained to 20°~40° using MOPLA. The tectonic evolution of the QOB from the late Paleozoic to early Mesozoic is illustrated.

Multiscale modeling, Flow partitioning, Structural analysis, Tectonic evolution, Shangdan tectonic zone, Qinling orogenic belt

Co-Authorship Statement

An earlier version of Chapter 2 in this thesis was published as a co-authored paper with my supervisor, Dr. Dazhi Jiang, and Lucy X. Lu (PhD student supervised by Dr. Dazhi Jiang).

Qu, M., Jiang, D., Lu, L.X. 2016. An optimal scheme for numerical evaluation of Eshelby tensors and its implementation in a MATLAB package for simulating the motion of viscous ellipsoids in slow flows. *Computers & Geosciences* 96 (2016): 98-108.

Dr. Jiang thoroughly edited the manuscript and L.X. Lu wrote some part of the MATLAB code in the paper.

Dedication

This work is dedicated to my parents, Qingxia Li and Lin Qu, for their love.

Acknowledgements

While working on the graduate program in Western University, I have benefited greatly from a large group of people.

First and foremost, I thank my supervisor, Dr. Dazhi Jiang, for the continuous support of my PhD research, for his immense knowledge on structural geology and tectonics, the never-ending enthusiasm and motivation in different research fields, caring and encouragement during my study at Western and my life in Canada. The accomplishment of this thesis would not be possible without his help.

Besides my supervisor, I thank the rest of my thesis committee: Dr. Richard Secco and Dr. Desmond Moser, for their encouragement, insightful suggestions, comments and questions during the comprehensive exam and the committee meeting. I also thank Dr. Desmond Moser for the extra help on the geochronological studies, and I thank Dr. Richard Secco for the suggestions and comments on the preliminary version of this thesis.

In addition, I thank Dr. Robert Shcherbakov and Dr. Colin Denniston for the two excellent courses that I have taken. One is ‘Computer Modelling of Natural Processes’ given by Dr. Robert Shcherbakov. During this course, I was surprised by the powerfulness of MATLAB, and thus motivated to move most of my programming work from MathCad to MATLAB. The other course is ‘Scientific Computing’ given by Dr. Colin Denniston in Applied Mathematics department. In this course, I have learned how efficient the computation could be in a parallel computing program. Although I do not have time to apply the parallel computing in my current research, I will definitely apply it into my future work.

My sincere thanks also go to my field assistants. In the order of their participation, they are Wenhong Liu, Yuanzhen Yang, Weiyin Chen, Lujun Lin, Teng Wang, Bo Zhang, Rui Yang in summers 2013-2016. I would like to thank Dr. Wei Li and Dr. Wentian Liang in Northwest University for the field guidance in east Qinling and west Qinling, respectively. Without their help, I would not have smoothly and happily conducted the field work during the summer times.

Finally, great thanks give to my family and friends for their love and supports in various aspects. Especially, I thank my colleague Rui Yang for performing the U-Pb dating of samples from the Shetang and Xinyang areas using a laser ablation inductively coupled plasma mass spectrometry at Northwest University. I thank Jiao Zhao for suggestions on processing U-Pb data. I thank Dr. Shuo Sun for the companion during the dark days. I thank my roommate and colleague Lucy Lu for the delicious food, great tea, encouraging words, good discussions and help on writing and debugging. I thank my parents for always trusting me, for giving me all their love and always being there for me.

Nomenclature

Symbol quantities

a_1, a_2, a_3, a_i	the semi-axes of an ellipsoid (first, second, third, general)
A	strain-rate partitioning tensor (fourth order) for linear materials or strain partitioning tensor for elastic materials
α	boundary convergence angle of a transpression zone
B	stress partitioning tensor (fourth order) for linear materials
β	dip angle of a transpression zone or a high-strain zone
C	elastic moduli or viscous stiffness tensor (fourth order)
C	linearized viscous stiffness tensor
$\bar{\mathbf{C}}$	HEM viscous stiffness tensor
δ	microscale characteristic length
δ_{ij}	Kronecker delta
δt	time step for numerical computation
d	mesoscale characteristic length
D	macroscale characteristic length
\mathcal{D}	characteristic length of the whole deformation body
e	elastic strain tensor in the ellipsoid)

E	elastic strain or viscous strain-rate tensor in the far-field matrix or HEM (symmetric part of L in viscous case)
$\boldsymbol{\varepsilon}, \tilde{\boldsymbol{\varepsilon}}$	viscous strain-rate tensor (general or in the ellipsoid), strain-rate difference between the ellipsoid and the far-field matrix
F	position gradient tensor (second order)
J^D , J^A	4 th order deviatoric and anti-symmetric identity tensors
L	velocity gradient tensor of matrix flow (second order)
λ	fluctuation length of boundary loading or velocity conditions
m	the strength of the anisotropy
Q	transformation matrix defined by the orientation of an ellipsoid
$\overline{\boldsymbol{\Theta}}$	angular velocity tensor of an ellipsoid
n	power law stress exponent
η_n, η_s	foliation-normal viscosity, foliation-parallel viscosity viscosity ratio between ellipsoid and matrix medium
r, r_{eff}, r_0	(Newtonian, effective where one or both the ellipsoid and the matrix medium are power law, effective at the matrix medium strain-rate state)
$\boldsymbol{\sigma}, \boldsymbol{\sigma}, \boldsymbol{\sigma}^0$	Cauchy stress tensor (general or in the ellipsoid), stress difference between the ellipsoid and the far-field

	matrix, pre-stress term in a linearized constitutive relation
Σ, Σ^0	Cauchy stress tensor in the far-field matrix or HEM, pre-stress term in a linearized rheological relation for the far-field matrix or HEM
\mathbf{S}	symmetric Eshelby tensor for incompressible viscous materials
$\mathbf{\Pi}$	anti-symmetric Eshelby tensor for incompressible viscous materials
\mathbf{T}	Green interaction tensor for incompressible viscous materials
\mathbf{w}, \mathbf{W}	vorticity, vorticity difference between the ellipsoid and the far-field matrix medium
\mathbf{W}	vorticity of the far-field matrix or HEM, anti-symmetric part of \mathbf{L}
$\boldsymbol{\omega}$	elastic rotation tensor

Chapter 1: Introduction

1.1. The multiscale problem in structural geology studies

Classical continuum models have been well studied and applied to structural analysis to interpret the relationship between fabrics and flow fields in homogeneous rock units (e.g., Ramsay, 1967; Ramsay and Graham, 1970; Ramberg, 1975; Passchier and Trouw, 1996). To identify the structural geometries and kinematics of a deformation zone, one conducts detailed structural analysis and geochronological studies in key areas and then in most cases, attempts to deduce the tectonic evolution of the zone. Field studies generally begin with observations of features at outcrop scale (i.e., a scale of a few millimeters to several meters). Studies then may proceed ‘downscale’ to observations made at the microscopic or even electron-microscopic level of microns, or ‘upscale’ to regional observations on a scale of hundreds to thousands of kilometers (Fig.1.1, Bruce and Ord, 2015). However, when one must analyze structures for a wide range of characteristic lengths in a single problem, the rheological heterogeneities of the lithosphere cause flow partitioning (Lister and Williams, 1983; Jiang, 2014). Structural geology studies on relatively small-scale features (‘minor structures’ in Jiang, 2013) are disconnected from large-scale tectonic synthesis. This scale problem has been recognized for many decades in structural geology studies (e.g., Lister and Williams, 1979, 1983; Jiang, 1994a,b; Jiang and White, 1995; Jiang and Williams, 1999). During the deformation of the lithosphere, the ‘bulk’ or ‘regional’ flow is partitioned into different small-scale rheologically distinct domains, and the final structures and fabrics are produced directly by the partitioned flow fields in ‘local’ domains (Fig.1.2). ‘Partitioning’ is generally used as a qualitative concept to, sometimes, ‘explain’ observations that do not fit the

predictions of simple models, or, at other times, critique simple-minded extrapolations from small-scale observations to large-scale processes. The use of small structures to infer tectonic processes is impeded if ‘partitioning’ is not considered quantitatively. Classical single-scale models cannot effectively address the heterogeneous deformation (Jiang, 2014). Therefore, a multiscale approach is necessary to link small-scale geological observations to large-scale tectonic synthesis.

Figure 1.1 Spatial scales associated with the deformation of Earth’s lithosphere. The blue arrows show the ‘upscale’ processes, the red arrows show the ‘downscale’ processes (Bruce and Ord, 2015).

Recently, Jiang and Bentley (2012) and Jiang (2013, 2014) have developed a multiscale approach, called the multi-order power-law approach (MOPLA), based on micromechanics to

quantitatively deal with ‘partitioning’ and bridge the scale gap between small-scale structures and large-scale tectonic synthesis.

Figure 1.2 Heterogeneous deformation throughout Earth’s lithosphere (modified after Jiang, 2014). (a) illustrates a crustal-scale deformation zone. (b) is a small region in the deformation zone and composed of transposed deformation domains. (e) and (f) are variable structures that are observed on outcrops. (c) and (d) are the microstructures observed under microscopes. (c)-(f) are directly produced by the ‘local’ flow fields in each domain in (b).

1.2. MOPLA

MOPLA stands for the multi-order power-law approach. MOPLA was built up to effectively address the heterogeneous deformation throughout the rheologically heterogeneous

lithosphere. MultiOrder means that with the idea of ‘elements within elements’, one can investigate rheological elements with multiple characteristic lengths, from relatively large (lower-order) elements (e.g., a deformed geological unit) to small (high-order) elements (e.g., fabric-defining elements inside the deformed geological unit) using MOPLA. Power-Law indicates that MOPLA considers deformed rocks as power-law viscous materials that reflect the rheological behavior of rocks for ductile deformation (Tullis et al., 1991; Kohlstedt et al., 1995). The theoretical formulations of MOPLA have been fully developed in Jiang (2014, 2016), and the algorithms are implemented in MathCad and MATLAB.

1.2.1 The aim of MOPLA

The aim of MOPLA is to effectively investigate the heterogeneous deformation that is mainly caused by the rheological heterogeneities in Earth’s lithosphere and to bridge the scale gap between the small-scale observations to large-scale tectonic synthesis.

The idea of MOPLA is illustrated in Fig.1.3. Fig.1.3 considers three different scales, and they are, from large to small, the *macroscale*, the *mesoscale* and the *microscale*. According to the nature of a problem, one can consider more scales if necessary. There are many orders of magnitude differences among the characteristic lengths of the three scales, and the absolute lengths depend on exact problems. In Fig.1.3, the deformation in a crustal-scale zone is regarded as the macroscale deformation (Fig.1.3a) with a characteristic length of \mathcal{D} . The statistically homogenous macroscale fields (‘regional’ stress, strain-rate and vorticity fields) are defined in terms of a Representative Volume Element (RVE) at every location (\mathbf{X}) with a characteristic length of D (Fig.1.3b). If a neighbor location (\mathbf{X}' in Fig.1.3b) is considered, the RVE is slightly shifted but most parts overlap with the previous RVE. The RVE is a large enough volume element containing a representative assemblage of all Rheologically Distinct Phases (RDPs) with a characteristic

length of d (Fig.1.3c). D , the size of the RVE, represents the macroscale characteristic length. D must be sufficiently smaller than the characteristic dimensions \mathcal{D} of the whole deformation zone, and smaller than the fluctuation length λ of the boundary loading. Namely, $D \ll \mathcal{D}$ and $D \ll \lambda$.

The mesoscale fields ('local' stress, strain-rate and vorticity fields) are regarded as the field quantities in individual rheological heterogeneities. Rheological heterogeneities may vary in size, but one can always divide larger rheological heterogeneities into smaller units, so that in a single problem, all RDPs have similar sizes with a characteristic length, d , in a macroscale RVE, and $d \ll D$. We assume d is small enough that the deformation fields inside each RDP are uniform. The shape of an RDP is approximated by an ellipsoid (Fig.1.3d). An RDP interacts with a Homogeneous Effective Medium (HEM) that is the homogenized medium on the RVE (Fig.1.3d).

The microscale features with a characteristic length of δ can be considered as the structures and fabric elements within mesoscale RDPs. They can be structures that are directly observed on outcrops (Fig.1.3e), or they can be the microstructural shape and lattice fabrics under microscope (Fig.1.3f, g) if the deformation in an RDP is homogeneous down to the microscopic scale. The condition, $\delta \ll d$, is assumed so that the microscale elements do not break the assumption that the mesoscale deformation inside each RDP is uniform.

In summary, the scale gaps among the microscale, the mesoscale and the macroscale can be expressed as $\delta \ll d \ll D \ll \mathcal{D}$, $D \ll \lambda$. This scale separation condition is the basis to regard mesoscale RDPs as Eshelby inhomogeneities in a macroscale deforming RVE and microscale fabrics as inclusions in partitioned fields in RDPs. The characteristic length scale description is not rigorous. The same method is used at different length scales if the material at the smallest scale is still a continuum body (i.e., micron scale and above in Fig.1.1). For a scale lower than microns,

a discrete particle system made of atoms or molecules, and molecular dynamics (MD) and quantum mechanics are used to study the behavior of the material (e.g., Ollila et al., 2013).

As we assume that the deformation fields within mesoscale RDPs are uniform, microscale and mesoscale field quantities are the same for each RDP. The macroscale field quantities can be related to microscale field quantities by definition (Hill, 1963; 1967; Jiang, 2014):

$$\mathbf{\Sigma}(\mathbf{X}) = \frac{1}{V} \int_V \mathbf{\sigma}(\mathbf{x}) dV = \langle \mathbf{\sigma} \rangle \quad (1.1a)$$

$$\dot{\mathbf{E}}(\mathbf{X}) = \frac{1}{V} \int_V \dot{\mathbf{\epsilon}}(\mathbf{x}) dV = \langle \dot{\mathbf{\epsilon}} \rangle \quad (1.1b)$$

$$\mathbf{W}(\mathbf{X}) = \frac{1}{V} \int_V \mathbf{w}(\mathbf{x}) dV = \langle \mathbf{w} \rangle \quad (1.1c)$$

where $\mathbf{\Sigma}$, $\dot{\mathbf{E}}$ and \mathbf{W} are respectively macroscale stress, strain-rate, and vorticity; $\mathbf{\sigma}$, $\dot{\mathbf{\epsilon}}$ and \mathbf{w} are respectively microscale stress, strain-rate and vorticity; \mathbf{X} and \mathbf{x} represent the macroscale and microscale locations respectively; V is the volume of the RVE, and the operator $\langle \bullet \rangle$ indicates the volume average value over the RVE.

The inverse relations of the Eqs.1.1 are to obtain the partitioned mesoscale flow fields within RDPs from imposed macroscale fields and can quantitatively solve the flow partitioning problem caused by the rheological heterogeneities of the lithosphere (Lister and Williams, 1983). The extended Eshelby theory is used to solve the partitioned fields in MOPLA and will be introduced in the next section.

Figure 1.3 A multiscale approach to study natural deformation (modified after Jiang, 2014).

See text for detailed explanation.

1.2.2 The backbone theory of MOPLA

The backbone theory of MOPLA is the extended Eshelby formalism for power-law viscous materials (Jiang and Bentley, 2012; Jiang, 2013, 2014). The classical Eshelby inclusion problem deals with an elastic ellipsoidal inclusion embedded in an infinite uniform elastic medium. Eshelby (1957, 1959) gave the expressions of the mechanical fields inside the inclusion (the interior fields) and around the inclusion (the exterior fields) in terms of the far-field mechanical fields. Eshelby (1957) solved the problem by proceeding a thought experiment on the possible mechanical fields in a linear elastic medium containing an inclusion. He considered the situation where the inclusion has undergone a transformation and correspondingly needed to change shape and size to accommodate the transformation, but the change is restricted due to the surrounding material (Fig.1.4). Eshelby (1957) used a ‘sequence of imaginary cutting, straining and welding operations’ and found that the resulting elastic field can be obtained.

Mura (1987) summarized Eshelby’s work of an inhomogeneity inclusion inside a matrix. The general solution of an elastic inhomogeneity problem is expressed by the following set of equations (Jiang 2014, his Eqs.9):

$$\mathbf{e} = \mathbf{A} : \mathbf{E}, \quad \mathbf{A} = \left[\mathbf{J}^s + \mathbf{S} : (\mathbf{C}_M^{-1} : \mathbf{C}_E - \mathbf{J}^s) \right]^{-1} \quad (1.2a)$$

$$\boldsymbol{\omega}^E = \boldsymbol{\omega}^M + \boldsymbol{\Pi} : \mathbf{S}^{-1} : (\mathbf{e} - \mathbf{E}) \quad (1.2b)$$

$$\boldsymbol{\sigma} = \mathbf{B} : \boldsymbol{\Sigma}, \quad \mathbf{B} = \mathbf{C}_E : \mathbf{A} : \mathbf{C}_M^{-1} \quad (1.2c)$$

where \mathbf{e} , $\boldsymbol{\omega}^E$, and $\boldsymbol{\sigma}$ are strain, rotation and stress fields inside inhomogeneity, respectively; \mathbf{E} , $\boldsymbol{\omega}^M$ and $\boldsymbol{\Sigma}$ are corresponding macroscale fields in infinite matrix; \mathbf{C}^E and \mathbf{C}^M represent the elastic stiffness inside inhomogeneity and matrix, respectively; \mathbf{A} and \mathbf{B} are respectively strain partitioning tensor and stress partitioning tensor; \mathbf{S} and $\boldsymbol{\Pi}$ are two 4th order Eshelby tensors.

Figure 1.4 An Eshelby inclusion in an infinite linear elastic medium. The stiffness tensor of the medium is C_0 , and the stiffness tensor of the inclusion is C_i . A transformation strain changes the shape and orientation of the inclusion. The matrix is with the characteristic length of D that is much larger than the size of the inclusion.

The above solutions have been extended to isotropic Newtonian viscous materials (Bilby et al., 1975; Bilby and Kolbuszewski, 1977) and to nonlinear viscous power-law materials through the linearization approach (e.g., Hutchinson, 1976; Molinari et al., 1987; Lebensohn and Tomé, 1993; Masson et al., 2000; Lebensohn et al., 2003, 2004; Jiang 2013, 2014).

1.2.3 Homogenization systems in MOPLA

The above extended Eshelby theory for power-law viscous materials is for an isolated Eshelby inhomogeneity embedded in an infinite homogeneous matrix. In MOPLA, every mesoscale RDP is treated as an Eshelby inhomogeneity embedded in an effective Homogeneous Effective Medium (HEM, Figs. 1.3d, 1.5), and the calculation of the mesoscale field quantities of RDPs from the macroscale field quantities is the partitioning process. The rheological properties of HEM are represented by the overall rheological properties of the RVE. The process to calculate

the rheological properties of HEM from the overall properties of the RVE is called homogenization. The homogenization process is based on the extended Eshleby theory as well (Jiang, 2014).

Figure 1.5 A conceptual diagram to show the two types of homogenization schemes in MOPLA (modified after Qu et al., 2016). (a) The Mori-Tanaka homogenization scheme is used for a composite material with crowded inclusions embedded in a connected matrix representing. (b) The self-consistent homogenization scheme is used for a continuum of poly-elements without a matrix phase. (c) The rheological properties of the homogeneous effective medium (HEM) are the ‘average’ from all the constituent elements in (a) or (b).

An RVE can be considered as a composite material, and there are two ways to proceed homogenization in MOPLA. One is the self-consistent system (Fig.1.5b) (Jiang, 2014), and the another is the Mori-Tanaka system (Fig.1.5a) (Mori and Tanaka, 1973). For composite materials such as polycrystalline materials without a distinct matrix phase, the self-consistent

homogenization scheme is used. For a composite material with inclusions embedded in a connected matrix, especially the concentration of the matrix phase should be around 25%-30%, the Mori-Tanaka homogenization method (Mori and Tanaka, 1973; Mercier and Molinari, 2009) is adopted.

In both systems, the partitioning and homogenization processes run in a self-consistent fashion. The initial rheological properties of RDPs are known, but, as the power-law viscous materials are considered, the actual viscous compliances (or stiffnesses) in RDPs are unknown until the mesoscale stress or strain-rate fields in RDPs obtained. Simultaneously, to calculate the partitioned mesoscale field quantities in RDPs, the rheological properties of HEM that are from the instantaneous viscous compliance (or stiffness) are required (Fig.1.5). The detailed equations are in Jiang (2014).

1.3. Application to the Shangdan tectonic zone in the Qinling orogenic belt

So far, MOPLA has only been applied to the Cascade Lake shear zone in the eastern Sierra Nevada region of California (Jiang and Bentley, 2012; Jiang, 2014), and more work is needed to explore possible fabric patterns for different sets of boundary conditions and model parameters. In this thesis, MOPLA is applied to the data-rich Shangdan tectonic zone (SDTZ) in the Qinling orogenic belt (QOB) to investigate the tectonic evolution of the QOB.

1.3.1 The problem in the QOB studies

The QOB separates China into the North China Block (NCB) and the South China Block (SCB), and it links the Kunlun, Qilian orogens in the west and the Dabie orogen in the east. The

Kunlun, Qilian, Qinling and Dabie orogens together are called the Central China Orogenic Belt (Fig.1.6, Dong et al., 2015).

Figure 1.6 A simplified tectonic map of China showing the major tectonic units and central China orogenic belt (the red-line area) (modified after Dong et al., 2015).

The main morphology of the QOB resulted from the final Triassic collision between the NCB and SCB, and the Cenozoic extension across China, but the QOB is a long-lived orogen and has experienced accretional and collisional processes since the Precambrian (Dong and Santosh, 2016 and references therein). The QOB is divided into two major belts, the North Qinling Belt (NQB) and the South Qinling Belt (SQB), by the Shangdan suture (Fig1.7). The Shangdan suture is Paleozoic and marked by discontinuously exposed ophiolite mélangé, clastic sedimentary rocks

and carbonates (Zhang et al., 2001; Dong et al., 2011a,b; Dong and Santosh, 2016). The Shangdan suture and its adjacent areas are referred to as the Shangdan tectonic zone (SDTZ) in this work. Because the western and eastern parts of the QOB show distinctive features (Zhang et al., 2001), the QOB is roughly divided into the western Qinling belt and the eastern Qinling belt by $\sim 108^{\circ}\text{E}$ (Fig1.7, Zhang et al., 2001).

In eastern Qinling, sub-vertical foliations and sub-horizontal stretching lineations with sinistral shear-sense indicators have been observed in mylonites along the SDTZ (Mattaueer et al., 1985; Xu et al., 1986; Zhang et al., 1989; Reischmann et al., 1990; Wang et al., 2005), and the fabrics indicate a sinistral strike-slip deformation. However, the age of this deformation and how it is related to the tectonic evolution of the QOB are still unclear. The detailed field work is conducted along the SDTZ in eastern Qinling in order to investigate the above questions.

In western Qinling, the NQB and Shangdan suture are not well established, and the structural features are unclear due to the cover of the Quaternary. With the guidance of Dr. Wentian Liang at Northwest University, we were able to find a shear zone, called the Xinyang-Yuanlong shear zone, in western Qinling. This shear zone was recognized in 2004 during a 1:250,000 regional geological mapping project and mapped as the boundary between the QOB and the Qilian orogen. It is also suggested as the western extension of the SDTZ by some researchers. The Xinyang-Yuanlong shear zone is studied in detail to address the following questions: what the geometric structures and kinematics of the zone and the corresponding deformation time are; how this shear zone relates to the deformation in eastern Qinling; whether this shear zone is the SDTZ in western Qinling.

Figure 1.7 A geological map of Qinling orogenic belt and its adjacent areas. KPS: the Neoproterozoic Kuanping suture; SDS: the Paleozoic Shangdan suture; MLS: the Triassic Mianlue suture; BXDS: the Neoproterozoic Bikou-Xiaomoling-Douling subduction zone; MHS: the Neoproterozoic Micangshan-Huangling subduction zone; LLWF: the Lingbao-Lushan-Wuyang fault; MBXF: the Mianlue-Bashan-Xiangguang fault; YYSZ: the Xinyang-Yuanlong shear zone. The grey part in the left-up corner map showing the location of the Qinling-Dabie orogen in China (Dong and Santosh, 2016).

Overall, in this thesis, the detailed field work and geochronological studies are conducted along the SDTZ in the western and eastern QOB, and the outcrop-scale fabrics are used to extrapolate the tectonic-scale boundary conditions by applying MOPLA to the field work areas.

1.3.2 The framework of the QOB

The first recorded study in the Qinling Mountain was a field investigation from Baoji to Hanzhong by F. Von Richthofen, a German, in the year of 1866 (Zhang et al., 2001). Since then, a lot of route surveys and preliminary geological inquiries were carried out in the Qinling Mountain (Zhao and Huang, 1931 as cited in Zhang et al., 2001). Since the 1950s, regional geological surveys were started in the Qinling Mountain. In the early 1980s, the first geological map of the Qinling Mountains on a scale of 1:200000 was completed, and several geochemical and geophysical studies were carried out (Zhang et al., 2001).

Over the past three decades, many studies have shown that the QOB was produced by the collisions among the micro-continents between the NCB and the SCB and the terminal collision of the NCB and the SCB (e.g., Mattatuer et al., 1985; Zhang et al., 1989; Enkin et al., 1992; Ames et al., 1996; Hacker et al., 1998; Meng and Zhang, 1999, 2000; Faure et al., 2001; Zhang et al., 2001; Ratschbacher et al., 2003, 2006; Dong et al., 2011a,b,c, 2012; Bader et al., 2013a,b; Dong and Santosh, 2016). At present, the Qinling orogen is bounded by the Lingbao-Lushan-Wuyang fault (LLWF) in the north and the Mianlue-Bashan-Xiangguang fault (MBXF) in the south (Fig1.7). It extends more than 1500km from west to east across central China, and it links Dabie

Mountains in the east and Qilian and Kunlun Mountains in the west. The QOB is generally divided into four tectonic belts that are the Southern North China Block (S-NCB), the North Qinling Belt (NQB), the South Qinling Belt (SQB) and the Northern South China Block (N-SCB) by 3 major sutures (i.e., the Neoproterozoic Kuanping suture, the Paleozoic Shangdan suture and the Triassic Mianlue suture) from north to south (Meng and Zhang, 2000; Zhang, et al., 2001; Dong et al., 2011a).

1.4. Objectives and methodology

The main objective of this thesis is to investigate the tectonic evolution of the SDTZ and to refine existing tectonic models for the QOB. Considering the distinctive features of western Qinling and eastern Qinling, the field study of the SDTZ in this thesis is correspondingly divided into the eastern part and the western part (Figs1.7,1.8).

Figure 1.8 A satellite map to show the field work areas. Red and yellow dots are the traces along the SDTZ in eastern Qinling, and the blue dots are the footprints along the Xinyang-Yuanlong shear zone in western Qinling.

The detailed structural mapping is conducted to reveal the spatial changes of fabrics using a Trimble Yuma differential Global Position System (GPS) with 1-to-2-meter accuracy. To relate the deformation with the tectonic evolution of the QOB, the deformation time is constrained by regional structural correlation and geochronology studies. U-Pb Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS) Zircon dating of the deformation-related dykes is used for the geochronological studies in this thesis. MOPLA is applied to research areas and used to simulate fabrics produced by partitioned flow fields, in order to infer the tectonic-scale boundary conditions.

1.5. Thesis outline

This thesis investigates the deformation of the SDTZ in eastern Qinling and the Xinyang-Yuanlong shear zone in western Qinling using MOPLA. There are six chapters. Chapter 1 provides a general introduction to this thesis. Chapter 2 develops an optimal scheme to efficiently evaluate the Eshleby tensors and implements the scheme into a MATLAB package to improve the computational efficiency of MOPLA. Chapter 3 studies the deformation of the SDTZ in eastern Qinling. Chapter 4 studies the deformation of the Xinyang-Yuanlong shear zone in western Qinling and integrates the previous results in eastern Qinling (i.e., Chapter 3) and discusses the tectonic synthesis of the deformation along the SDTZ in the QOB. Chapter 5 summarizes the contribution of this work and the future work of this study.

Chapter 2: An Optimal Scheme for Numerical Evaluation of Eshelby Tensors and Its Implementation in a MATLAB Package for Simulating the Motion of Viscous Ellipsoids in Slow Flows

2.1 Introduction

The motion of a heterogeneous inclusion dispersed in a continuous matrix has been the subject of research for over a century (e.g., Einstein, 1896, 1911, as cited by Jeffery 1922; Jeffery, 1922; Eshelby, 1957; Goldsmith and Mason, 1967; Mura, 1987; Jiang 2013, 2014). The theories and their various modified versions have been widely applied to natural rock deformation and fabric development in the geological literature (e.g., Flinn, 1956; Ramsay, 1967; Gay, 1968; Dunnet, 1969; Bilby et al., 1975; Ferguson, 1979; Fry, 1979; Lisle, 1985; Freeman, 1985; Ježek et al., 1996; Jiang, 2007a,b; Meng et al., 2012; Xiang and Jiang; 2013; Chen et al., 2014). A brief history of this theoretical development is summarized below. Jeffery (1922) first derived equations for the angular velocity of a rigid ellipsoid embedded in an infinite isotropic Newtonian material undergoing far-field homogeneous flow. As many natural rocks resemble the system of a matrix containing rigid or nearly rigid inclusions, Jeffery's theory has been found many applications in geology (e.g., Passchier and Simpson, 1986; Simpson and De Paor, 1993; Vigneresse and Tikoff, 1999; Mancktelow et al., 2002; Johnson et al., 2009; Grier et al., 2013). For the more general case involving deformable inclusions, Bilby et al. (1975) and Bilby and Kolbuszewski (1977) extended Eshelby's (1957) pioneering work on an isotropic elastic ellipsoid embedded

in an infinite isotropic elastic solid undergoing far-field homogeneous deformation to isotropic Newtonian viscous materials. However, the general equations of Jeffery (1922), Bilby et al. (1975), and Bilby and Kolbuszewski (1977) do not have analytical solutions. For the Jeffery equations, analytical solutions have been found so far only for spheroids in monoclinic flows (e.g., Jeffery, 1922; Ježek et al., 1996; Jiang, 2007a). For viscous deformable inclusions, closed-form solutions have only been found for some simple and two-dimensional flows (e.g., Eshelby 1957; Bilby and Kolbuszewski, 1977). In general, Jeffery's and Eshelby's equations must be solved numerically. Freeman (1985) first numerically investigated the possible rotational behaviors of a rigid ellipsoid using Jeffery's theory for a variety of flow fields. He (Freeman, 1987) was also the first to use the equations of Bilby and Kolbuszewski (1977) to numerically analyze the motion of deformable ellipsoids in pure and simple shearing. Ježek (1994) developed FORTRAN programs to calculate the rotational path of individual rigid ellipsoids in any given flow field as well as the rotation and preferred orientation development for a system of multiple, but non-interacting, rigid ellipsoids. Jiang (2007a,b) developed algorithms and MathCad worksheets to numerically calculate the rotational path of individual rigid and deformable ellipsoids and the fabric evolution in a system of multiple non-interacting rigid or deformable ellipsoids. In his algorithms, a set of spherical angles (similar to plunge direction and plunge angle of a line in geology) was used to define the orientation of the ellipsoid instead of the Euler angles used in previous studies. Jiang (2012) further simplified the algorithms by using a single differential equation for rotation: $d\mathbf{Q}/dt = -\bar{\boldsymbol{\Theta}}\mathbf{Q}$ (where $\bar{\boldsymbol{\Theta}}$ is the angular velocity and \mathbf{Q} the matrix for the orientation of the ellipsoid). This is different from

using a set of three coupled differential equations for Euler angles in previous works (e.g., Ježek 1994). The use of a single differential equation greatly improves the computational efficiency. For dilute inclusions dispersed in a uniform matrix (Figs.2.1a, b) where the non-interaction assumption is valid, the numerical approach of Jiang (2012) provides an efficient and accurate means of numerical simulation.

Figure 2.1 A conceptual diagram to illustrate three different scenarios of a clast-matrix system. (a) An infinite medium subjected to a remote motion with strain rate \mathbf{E} , vorticity \mathbf{W} , and stress Σ . The macroscale deformation is defined, at every point, in terms of a Representative Volume Element (RVE) with strain rate $\bar{\epsilon}$, vorticity \bar{w} , and stress $\bar{\sigma}$. (b), (c) and (d) are the magnified illustrations of an RVE to show three different scenarios. (b) In the scenario, the inclusions are dispersed far apart from each other in a matrix; this is the dilute inclusion scenario in which the macroscale fields are similar to the infinite fields. (c) A composite material with more crowded inclusions embedded in a connected matrix: the matrix phase (C_0) is adopted as a reference medium to solve for the partitioned fields $(\epsilon^{(k)}, w^{(k)}, \sigma^{(k)})$ in each clast (C_k) (i.e., Mori-Tanaka scheme). The rheological properties of C_0 are the same as the Homogeneous Effective Medium (HEM) in (e). (d) An inclusion is in a polyelement continuum system without a matrix phase: HEM in (e) is adopted as a reference medium which has the macroscopic response of the material $(\bar{\epsilon}, \bar{w}, \bar{\sigma})$ and its rheological properties are the homogenized result of all the constituent elements in an RVE.

Eshelby's inclusion theory has also been extended to nonlinear viscous power-law materials through the so-called 'linearization approach' (e.g., Hutchinson, 1976; Molinari et al., 1987; Lebensohn and Tomé, 1993; Masson et al., 2000; Lebensohn et al., 2003, 2004; Jiang 2013, 2014). This extension forms the basis of the viscoplastic self-consistent (VPSC) theory (Molinari et al., 1987; Lebensohn and Tomé, 1993; Tomé and Lebensohn, 2008; Lebensohn et al., 2011) for simulating lattice preferred orientation fabrics in polycrystalline materials. Recently, the extended Eshelby theory has also been used in a self-consistent MultiOrder Power-Law Approach (MOPLA, Jiang and Bentley 2012; Jiang 2014) to address the multiscale heterogeneous deformation characteristic of Earth's lithosphere (Fig.2.1). In the latter, a macroscale

field variable at every point is represented by the average of the variable over a Representative Volume Element (RVE) (Fig.2.1a), which contains many rheologically distinct power-law viscous elements (Fig.2.1d). The mechanical fields in a constituent element (treated as an Eshelby inhomogeneity) are related to the macroscale fields by the extended Eshelby theory and the mechanical fields in constituent elements are used to model the development of small-scale fabrics within the elements (Jiang, 2014). To apply the extended Eshelby theory, the macroscale polyelement continuum is represented rheologically by a Homogeneous Effective Medium (HEM, Fig.2.1e), which is used as a reference medium for homogenization – the procedure to obtain the effective rheological properties of HEM. Self-consistent homogenizations (e.g., Molinari 2002) make use of the consistency conditions (macroscale compatibility and equilibrium) which require that the average of the local fields (within elements) over the representative volume of the polyelement be equal to those imposed at the macroscale ($\bar{\epsilon}, \bar{\omega}, \bar{\sigma}$ in Fig.2.1e). The one-site self-consistent approach (or the mean-field theory, Lebensohn and Tomé, 1993; Lebensohn et al., 1998) assumes that HEM is rheologically uniform. Local fields are partitioned fields of the macroscale field. The partitioned fields then dictate the fabric development in individual elements, and this constitutes the multiscale simulation of Jiang (2014). In the case where there is a clearly identified matrix phase (Fig.2.1c), the matrix can be considered a reference medium instead of HEM and the Mori-Tanaka (Mori and Tanaka, 1973) approach can be used for the homogenization (e.g., Mercier and Molinari, 2009).

One can appreciate that a self-consistent approach, such as MOPLA, is computationally intensive, because the partitioning calculation (to obtain local fields

from the macroscale field) and the homogenization calculation (to obtain HEM rheological properties from instantaneous local fields and constituent rheological properties) (Fig.2.1) must be performed self-consistently and this requires large numbers of iterative calculations, each involving a large number (for all constitutive elements) of evaluations of the Eshelby tensors. As deformation proceeds, the constituent elements become more elongated and/or flattened, and the HEM also becomes rheologically more anisotropic, both rendering the accurate evaluation of the Eshelby tensors for these elements ever more time-consuming. Therefore, an efficient scheme to evaluate Eshelby tensors is critical for self-consistent modeling. The main purpose of this paper is to develop an efficient scheme for evaluating Eshelby tensors. We also apply the efficient scheme to develop a MATLAB package for simulating the motion of single and multiple ellipsoids, upgrading the MathCad package of Jiang (2007a,b, 2012).

2.2 Numerical evaluation of Eshelby tensors

In this section, we first summarize the Eshelby inclusion solutions in order to introduce the Eshelby tensors. We then discuss numerical methods to evaluate the Eshelby tensors.

2.2.1 The Eshelby inclusion solutions and Eshelby tensors

The general Eshelby formalism for a viscous ellipsoidal inclusion (Molinari et al., 1987; Lebensohn et al., 1998) relates the local uniform fields inside a linear viscous ellipsoid (strain rate $\boldsymbol{\varepsilon}$, vorticity \boldsymbol{w} , and deviatoric stress $\boldsymbol{\sigma}$, all second-order tensors) to their far-field counterparts in the matrix (namely, the strain rate \boldsymbol{E} , vorticity \boldsymbol{W} ,

and deviatoric stress Σ) by the following set of relations (Fig.2.1) (e.g., Jiang, 2014, Eq.11 there, for incompressible materials):

$$\tilde{\boldsymbol{\varepsilon}} = (\mathbf{J}^D - \mathbf{S}^{-1})^{-1} : \mathbf{C}_M^{-1} : \tilde{\boldsymbol{\sigma}} \quad (2.1a)$$

$$\tilde{\mathbf{w}} = \mathbf{\Pi} : \mathbf{S}^{-1} : \tilde{\boldsymbol{\varepsilon}} \quad (2.1b)$$

$$\tilde{\boldsymbol{\sigma}} = \mathbf{C}_M : (\mathbf{J}^D - \mathbf{S}^{-1}) : \tilde{\boldsymbol{\varepsilon}} \quad (2.1c)$$

where the tilde above a quantity stands for the difference between the local field and that at infinity (e.g., $\tilde{\boldsymbol{\varepsilon}} = \boldsymbol{\varepsilon} - \mathbf{E}$), \mathbf{C}_M is the 4th-order viscous stiffness tensor of the matrix, \mathbf{J}^D is the 4th-order deviatoric identity tensor, as used in Jiang (2013, 2014), defined by $J_{ijkl}^D = \frac{1}{2}(\delta_{ik}\delta_{jl} + \delta_{jk}\delta_{il}) - \frac{1}{3}\delta_{ij}\delta_{kl}$ with $\delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}$, and \mathbf{S} and $\mathbf{\Pi}$ are, respectively, the symmetric and antisymmetric Eshelby tensors. The sign “:” stands for the double-index contraction operation between tensors (see Jiang 2013, 2014 for more details).

The set of Eqs.(2.1) is an exact solution for linear viscous materials. For nonlinear materials, there is no such exact solution. However, Eqs.(2.1) can be used as an approximate solution if the material’s nonlinear behavior is replaced by a linearized behavior, using the well-known linearization approach (e.g., Molinari et al., 1987; Lebensohn and Tomé, 1993). Through linearization, one can write the constitutive equations for the matrix and inclusion in approximate linear forms: $\Sigma = \hat{\mathbf{C}}_M : \mathbf{E} + \Sigma^0$, $\sigma = \hat{\mathbf{C}}_E : \boldsymbol{\varepsilon} + \sigma^0$, where $\hat{\mathbf{C}}_M$ and $\hat{\mathbf{C}}_E$ are, respectively, the linearized viscous stiffness for the matrix and the inclusion; Σ^0 and σ^0 are associated pre-stress terms (see Molinari et al., 1987; Lebensohn and Tomé 1993; Tomé and

Lebensohn, 2008; Lebensohn et al., 2011; Jiang, 2013, 2014 for details). Eqs.(2.1) can be used as a set of approximate solutions, e.g., $\tilde{\boldsymbol{\varepsilon}} = (\mathbf{J}^D - \mathbf{S}^{-1})^{-1} : \mathbf{C}_M^{-1} : \tilde{\boldsymbol{\sigma}}$, for nonlinear viscous materials. A variety of linearization approaches have been proposed (e.g., Hutchinson, 1976; Molinari et al., 1987; Lebensohn and Tomé, 1993; Masson et al., 2000; Lebensohn et al., 2003, 2004; Jiang 2013, 2014). A well-known one is the tangent linearization, in which $\hat{\mathbf{C}}$ is (e.g., Jiang, 2014, Eq.22 there)

$$\hat{\mathbf{C}} = \mathbf{C}^{(\text{tan})} = \frac{1}{n} \mathbf{C}^{(\text{sec})} \quad (2.2)$$

where $\mathbf{C}^{(\text{tan})}$ and $\mathbf{C}^{(\text{sec})}$ are the tangent and secant viscous stiffness tensors of a power-law material, and n is the power-law stress exponent for the material. The secant stiffness is also known as the effective viscosity (Ranalli, 1995, p.78).

The key to evaluating Eqs.(2.1) lies in the evaluation of the two Eshelby tensors (\mathbf{S} and $\mathbf{\Pi}$). For isotropic materials, this can be done using closed-form expressions or expressions involving the simple complete elliptic integrals of the first type and second type (Eshelby 1957; Mura 1987, p.77). For anisotropic materials, which are common in natural deformation and must be accounted for in self-consistent models such as MOPLA, VPSC or any self-consistent homogenization (e.g., Molinari, 2002; Molinari and Mercier, 2004; Mercier and Molinari, 2009), Eshelby tensors can only be evaluated numerically.

The two Eshelby tensors can be defined in terms of an auxiliary fourth order tensor \mathbf{T} , called the Green interaction tensor by Lebensohn et al. (1998). For incompressible materials, \mathbf{T} can be expressed as (e.g., Lebensohn et al., 2004; Jiang, 2014):

$$T_{ijkl} = \frac{a_1 a_2 a_3}{4\pi} \int_{\|\xi\|=1} \frac{\xi_j \xi_l A_{ik}(\xi)}{\left[(a_1 \xi_1)^2 + (a_2 \xi_2)^2 + (a_3 \xi_3)^2 \right]^{\frac{3}{2}}} d\xi \quad (2.3a)$$

$$\mathbf{S} = \mathbf{J}^D : \mathbf{T} : \mathbf{C}_M \quad (2.3b)$$

$$\mathbf{\Pi} = \mathbf{J}^A : \mathbf{T} : \mathbf{C}_M \quad (2.3c)$$

where a_1, a_2, a_3 are the three semi-axes of the ellipsoid, ξ is the unit vector variable,

$\hat{\mathbf{A}}_{ik}(\xi)$ is a symmetric 3×3 matrix related to the viscous stiffness of the matrix medium and is a function of ξ (see Lebensohn et al., 2004 and Jiang, 2014 for more details), and \mathbf{J}^A is the 4th-order anti-symmetric identity tensor with $J_{ijkl}^A = \frac{1}{2}(\delta_{ik}\delta_{jl} - \delta_{jk}\delta_{il})$ as used in Jiang (2013, 2014).

2.2.2 Numerical evaluation of T_{ijkl}

Calculating the Eshelby tensors boils down to evaluating the integral in Eq.(2.3a) efficiently. The integral can be expressed in terms of spherical angles using

the substitution $\xi = \begin{pmatrix} \cos \theta \sin \phi \\ \sin \theta \sin \phi \\ \cos \phi \end{pmatrix}$:

$$T_{ijkl} = \frac{a_1 a_2 a_3}{4\pi} \int_0^{2\pi} \left\{ \int_0^\pi [\mathbf{f}(\theta, \phi)]_{ijkl} \sin \phi d\phi \right\} d\theta \quad (2.4a)$$

where

$$[\mathbf{f}(\theta, \phi)]_{ijkl} = \frac{\xi_j \xi_l A_{ik}(\xi)}{\left[(a_1 \xi_1)^2 + (a_2 \xi_2)^2 + (a_3 \xi_3)^2 \right]^{\frac{3}{2}}} \quad (2.4b)$$

Jiang (2013, 2014) in his MathCad worksheets used the following product Gaussian quadrature for Eq.(2.4a):

$$T_{ijkl} \approx \frac{a_1 a_2 a_3}{4\pi} \sum_{q=1}^n \sum_{p=1}^n w_p w_q \left[f(\phi_q, \theta_p) \right]_{ijkl} \sin \phi_q \quad (2.5)$$

where (ϕ_q, θ_p) are Gauss-Legendre grid nodes, w_p are the Gauss-Legendre weights within $[-1, 1]$, and n is the number of nodes and weights. The total number of grid nodes used in Eq.(2.5) is thus n^2 . Atkinson (1982) presented a slightly different product Gaussian quadrature. Instead of discretizing both ϕ_p in $[0, \pi]$ and θ_p in $[0, 2\pi]$ according to the Gauss-Legendre method as in Jiang (2013, 2014), in Atkinson (1982), the grid nodes (ϕ_q, θ_p) are generated by discretizing $(\cos \phi)_p$ in $[-1, 1]$ based on the Gauss-Legendre formula while θ_p is evenly spaced within $[0, 2\pi]$. In this scheme T_{ijkl} is approximated by the following expression:

$$T_{ijkl} \approx \frac{a_1 a_2 a_3}{4n} \sum_{q=1}^{2n} \sum_{p=1}^n w_p \left[f(\phi_p, \theta_q) \right]_{ijkl} \quad (2.6)$$

where w_p are weights in $[-1, 1]$ using the Gauss-Legendre formula and the total node number is $2n^2$. We compared these two quadrature schemes in MATLAB for different ellipsoid shapes and found that the approximation of Eq.(2.5) consistently outperforms that of Eq.(2.6). Therefore, we shall use Eq.(2.5) when we adopt a product Gaussian quadrature and do not consider Eq.(2.6) any further in this paper.

A less well-known scheme for numerical integration over a unit sphere such as Eq.(2.3a) is the Lebedev quadrature (Lebedev, 1977) in which Eq.(2.4a) is approximated by:

$$T_{ijkl} \approx a_1 a_2 a_3 \sum_{p=1}^N w_p \left[f(\phi_p, \theta_p) \right]_{ijkl} \quad (2.7)$$

where the nodes and their associated weights are determined by the Lebedev quadrature rules. It is beyond the scope of this paper to describe the mathematical details of the Lebedev quadrature. Interested readers may refer to Lebedev (1977). Basically, the quadrature obtains spherical harmonics that are invariant under the octahedral group with inversion and yields exact integration for all spherical harmonics up to a given order (Lebedev, 1977). Geometrically, the Lebedev grid nodes correspond to the vertices of a geometric polyhedron with octahedral rotation and inversion symmetry, and all nodes from the same geometric polyhedron share the same weight defined below (similar to Lebedev, 1977, Eq.2.2 there):

$$T_{ijkl}^N(f) \approx a_1 a_2 a_3 \left\{ w^{(A^1)} \sum_{p=1}^6 \left[f(A_p^1) \right]_{ijkl} + w^{(A^2)} \sum_{p=1}^{12} \left[f(A_p^2) \right]_{ijkl} + w^{(A^3)} \sum_{p=1}^8 \left[f(A_p^3) \right]_{ijkl} + \right. \\ \left. \sum_{q=1}^{N_1} w^{(B^q)} \sum_{p=1}^{24} \left[f(B_p^q) \right]_{ijkl} + \sum_{q=1}^{N_2} w^{(C^q)} \sum_{p=1}^{24} \left[f(C_p^q) \right]_{ijkl} + \sum_{q=1}^{N_3} w^{(D^q)} \sum_{p=1}^{48} \left[f(D_p^q) \right]_{ijkl} \right\} \quad (2.8)$$

where N is the total number of nodes generated, $A^1, A^2, A^3, B^q, C^q, D^q$ are different sets of nodes associated with different geometric polyhedrons, and $w^{(A^1)}, w^{(A^2)}, w^{(A^3)}, w^{(B^q)}, w^{(C^q)}, w^{(D^q)}$ are their corresponding weights. The total number of nodes generated in Eq.(2.8) is $N = 26 + 24 \times (N_1 + N_2) + 48 \times N_3$. For example, the smallest set of Lebedev nodes is 6, corresponding to the vertices of a regular octahedron (A^1), and can be expressed by polar coordinates, $(1, \phi, \theta)$. The weight for these 6 nodes is the same (i.e., $w^{(A^1)}$).

By selecting the set of $(w, \phi$ and $\theta)$ simultaneously in a double integral, rather than discretizing ϕ and θ integrals separately as in the product Gaussian quadrature described above, Lebedev quadrature is more economic computationally. According to our MATLAB tests, the evaluation of T_{ijkl} [Eq.(2.4a)] using the Lebedev quadrature always outperforms the product Gaussian quadrature using Eq.(2.5) significantly, especially for elongate prolate-like ellipsoids. It would seem to suggest that one should always use the Lebedev quadrature to evaluate T_{ijkl} . However, the maximum of nodes and weights now available for the Lebedev quadrature is 5810 because of difficulties (Lebedev, 1975, 1976, 1977, 1995; Lebedev and Skorokhodov, 1992; Lebedev and Laikov, 1999) encountered when the order of spherical harmonics gets high. This limits the use of the Lebedev quadrature. Where even the maximum nodes and weights of the Lebedev quadrature cannot allow for accurate evaluation of T_{ijkl} , we must still use the product quadrature. There is an online library providing MATLAB code for computing Lebedev nodes and weights (Saff and Kuijlaars, 1997). We make use of this library and incorporate the Lebedev quadrature as an option to numerically evaluate Eq.(2.4a).

The error associated with evaluating Eq.(2.4a) using the product quadrature or the Lebedev quadrature with a given node number is unknown, *a priori*. One can easily build in an error estimate in either quadrature as follows: prescribing a tolerance and evaluating the integral iteratively, starting with a lower node number and progressively increasing the node number until the outputs converge within the prescribed tolerance. Alternatively, one can use an adaptive algorithm to evaluate Eq.(2.4a) in which a fixed number of nodes is applied on refined subintervals of the integration domain, and the

subintervals are partitioned into successively finer subdivisions until the prescribed tolerance is reached (e.g., Davis and Rabinowitz, 1975; Krommer, 1994; Quarteroni et al., 2010). Both the iterative and the adaptive approaches involve repetitive calculations. Because the adaptive approach selects the number of nodes based on local integrand behaviors, it is more economical than the iterative approach in general. To save computational resources, one would like to avoid any repetitive calculations if it is at all practical by prescribing, *a priori*, the node number of the product quadrature or the Lebedev quadrature to evaluate Eq.(2.4a). Our motivation in developing an optimal scheme in the following section is to avoid repetitive calculations as much as possible.

2.3 An optimal scheme

We note that it takes longer to evaluate Eq.(2.4a) as an ellipsoid becomes more elongate or flattened. In order to quantify this dependence, we use the Flinn parameters in structural geology (e.g., Ramsay, 1967; Hobbs et al., 1976) to quantify the shape of ellipsoids below and investigate how the computational time required to evaluate Eq.(2.4a) depends on the ellipsoid's Flinn parameters.

As shown in Fig.2.2, in the Flinn space, an ellipsoid shape is represented uniquely by two coordinates, $R = \sqrt{\ln^2(a_1/a_2) + \ln^2(a_2/a_3)}$ and

$\Phi = \arctan\left(\frac{\ln(a_1/a_2)}{\ln(a_2/a_3)}\right)$. R measures quantitatively the degree of elongation/flatness

of an ellipsoid and Φ measures the oblateness and prolateness of an ellipsoid. A sphere is plotted at the origin ($R = 0$), an oblate object on the abscissa ($\Phi = 0^\circ$), and a prolate object on the ordinate ($\Phi = 90^\circ$). A general triaxial ellipsoid is plotted in the quadrant

between the two. The $\Phi = 45^\circ$ line separates prolate-like objects from oblate-like ones (Fig.2.2).

Figure 2.2 Ellipsoid shape quantified by two parameters (R and Φ) in the Flinn space. Any ellipsoid is plotted as a point on the diagram. R measures the deviation of the ellipsoid from a sphere and Φ measures its oblateness and prolateness of the ellipsoid.

In order to find out how the computational time depends on R and Φ , we ran numerical calculations using the adaptive product Gaussian quadrature to evaluate Eq.(2.4a) for an isotropic matrix. The range of Φ is $[0^\circ, 90^\circ]$ to cover all types of

prolate-like and oblate-like ellipsoids. Natural deformations can reach extremely high strains. Therefore, in principle, the shapes of constituent elements can reach very high aspect ratios. We could have selected any R as the upper limit for our numerical tests. We have arbitrarily chosen $a_1 : a_3 = 100 : 1$ as the upper limit ($R=4.7$; $\ln 100 \approx 4.605$) in this paper. We believe that, for elements with even higher aspect ratios, treating them as ellipsoids becomes questionable as the uniform field assumption within such elements is unrealistic. We have also limited the matrix to be isotropic because we want to reveal the dependence of computation time solely on ellipsoid shape. There is an infinite number of possible choices if the matrix is anisotropic. We discuss this point further in Section 2.5. The numerical runs were carried out using MATLAB (version is R2015a) on an HP z820 Workstation with Intel Xeon E5-2690 CPU and 192GB RAM in a Windows 7 system.

Fig.2.3 is a contoured map showing the dependence of the computational time to numerically evaluate Eq.(2.4a) on ellipsoid shape using the adaptive product Gaussian quadrature. For each given ellipsoid (Φ and R), the time in Fig.2.3 represents the total time needed to evaluate Eq.(2.4a) 100 times. We use 100 times of evaluation to reduce system turbulence effect on the computational time. Fig.2.3 shows clearly that the computational time increases with Φ and R in general, confirming the known observation that more elongate/flattened ellipsoids require longer computation to get their Eshelby tensors. The red dashed lines in Fig.2.3 are a_1 -isolines. For example, the ‘ $a_1 = 100$ ’ isoline represents ellipsoids with three semi-axes being $100 : a_2 : 1$, where a_2 varies from 1 ($\Phi = 90^\circ$) to 100 ($\Phi = 0^\circ$).

In principle, the contour lines in Fig.2.3 can be used as criteria to assign node numbers according to ellipsoid shapes. However, these lines are rather irregular, so we generate smoother curves empirically to mimic the contour lines in Fig.2.3 and use these curves as criteria to assign proper node numbers. These curves are $R = f_1(\Phi)$,

Figure 2.3 The contour plot of computation time (s) with respect to R and Φ . Contour levels are 5, 10, 15, 20, 25, 40, 80 and 160s from low to high values of the computation time. Red dashed lines are a_1 - isolines ($a_1 = 10$, $a_1 = 50$, $a_1 = 100$, $a_1 = 300$, details refer to the text).

$R = f_2(\Phi)$, $R = f_3(\Phi)$, $R = f_4(\Phi)$ in Fig.2.4 and they divide the shape space (Fig.2.3) into five domains (Fig.2.4). The mathematical expressions of the curves are given in Appendix A. The computational time in Fig.2.3, which is based on the

adaptive product Gaussian quadrature, reflects the behaviour of the integrand in Eq.(2.4a) and the required node number: a longer computational time means more recursions, which suggests that more nodes are needed for the Lebedev quadrature and product Gaussian quadrature, and vice versa. We wish to find an optimal quadrature (i.e., product Gaussian quadrature or Lebedev quadrature) and corresponding node number for each domain using iterative tests. The optimal quadrature and corresponding node numbers for Domains A, B, C, D are based on the iterative tests of $R = f_1(\Phi)$, $R = f_2(\Phi)$, $R = f_3(\Phi)$, $R = f_4(\Phi)$, respectively. For example, in order to set the quadrature and its corresponding node number for Domain A, we evaluate Eq.(2.4a) iteratively for all ellipsoids with R and Φ on f_i and choose the largest node number as the node number for Domain A to guarantee the accuracy. As explained in Section 2.2, the Lebedev quadrature is the best option to evaluate Eq.(2.4), and when the maximum node number of the Lebedev quadrature (5810) is not sufficient accurately evaluate Eq.(2.4a), we use the product Gaussian quadrature. In one domain, such as Domain A, the Lebedev quadrature generally requires fewer nodes for prolate-like ellipsoids than oblate-like ellipsoids, so we further divide one domain into two subdomains according to Φ and set a more appropriate node number for each subdomain. For Domain E, the required node number for the product Gaussian quadrature is 650^2 (i.e., PGQ(650^2)). This would require more computational time than the adaptive product Gaussian quadrature. Therefore, for ellipsoids fall in Domain E, an adaptive product Gaussian quadrature is the best choice. In summary, the optimal scheme works as follows: According to the instantaneous three axes of an ellipsoid, we can calculate its Φ and R , based on which the domain for the ellipsoid is

decided. If the ellipsoid falls in Domain E, the adaptive product Gaussian quadrature is used to evaluate Eq.(2.4a), otherwise its Φ value is used to decide further what subdomain the ellipsoid is in. The optimal quadrature and associated node number are then selected for the ellipsoid to evaluate Eq.(2.4a).

Figure 2.4 Optimal quadrature and associated node numbers for different shapes of the inclusion according to the iterative tests. ‘LbdvQ’ stands for the Lebedev Quadrature and ‘PGQ’ stands for the Product Gaussian Quadrature.

2.4 A MATLAB package for simulating the motion of rigid and deformable inclusions

The optimal scheme developed above can be applied in any model that involves the numerical integration of Eq.(2.4a). As a demonstration of its use, we

implement it in a MATLAB package for the motion of rigid and deformable ellipsoids in ductile flows.

2.4.1 A brief summary of important equations for rigid and deformable ellipsoids

The rotation of a rigid or deformable ellipsoid in ductile flows is described by the following differential equation (Jiang, 2012):

$$\frac{d\mathbf{Q}}{dt} = -\bar{\boldsymbol{\Theta}}\mathbf{Q} \quad (2.9)$$

For deformable ellipsoids, the shape evolution with time is governed by

$$\frac{d\mathbf{a}}{dt} = \mathbf{D}^{\text{axis}}\mathbf{a} \quad (2.10)$$

where $\mathbf{a} = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix}$ and \mathbf{D}^{axis} is a diagonal matrix for the strain rates along the current

semi-axes, $D_{ij}^{\text{axis}} = \begin{cases} 0, & \text{if } i \neq j \\ \varepsilon_{ij}, & \text{if } i = j \end{cases}$. The angular velocity, $\bar{\boldsymbol{\Theta}}$, in Eq.(2.9) is determined

by the vorticity in an ellipsoid (Eq.(2.1b)) and a shear spin, \mathbf{w}^s (Jiang, 2012, 2013,

2014): $\bar{\boldsymbol{\Theta}} = \mathbf{W} + \boldsymbol{\Pi} : \mathbf{S}^{-1} : \tilde{\boldsymbol{\varepsilon}} - \mathbf{w}^s$, where $w_{ij}^s = \begin{cases} \frac{a_i^2 + a_j^2}{a_i^2 - a_j^2} \varepsilon_{ij} & a_i \neq a_j \\ w_{ij} & a_i = a_j \end{cases}$ (no sum). For

a rigid ellipsoid, $\tilde{\boldsymbol{\varepsilon}} \equiv -\mathbf{E}$ ($\varepsilon_{ij} \equiv 0$) and $w_{ij}^s \equiv 0$, the angular velocity is

$\bar{\boldsymbol{\Theta}}_{(\text{rigid})} = \mathbf{W} - \boldsymbol{\Pi} : \mathbf{S}^{-1} : \mathbf{E}$, which is a generalization of Jeffery's (1922) equation to a

general anisotropic viscous matrix. $\boldsymbol{\varepsilon}$ (i.e., \mathbf{D}^{axis} in Eq.(2.10)) can be obtained from

Eq.(2.1a) by using the general constitutive equations for the matrix and the inclusion

(i.e., $\boldsymbol{\Sigma} = \mathbf{C}_M : \mathbf{E}$ and $\boldsymbol{\sigma} = \mathbf{C}_E : \boldsymbol{\varepsilon}$): $\boldsymbol{\varepsilon} = [\mathbf{J}^p - \mathbf{S} + \mathbf{S} : \mathbf{C}_E : \mathbf{C}_M^{-1}]^{-1} : \mathbf{E}$.

Eqs.(2.9) and (2.10) can be solved numerically by using the Runge-Kutta method (Jiang, 2012), the Rodrigues approximation (Jiang, 2013), or a combination of both (Jiang 2014). We apply the tangent linearization (i.e., Eq.(2.2)) in the MATLAB package, so the package can be used for power-law viscous materials. The package is written in MATLAB generally. For better performance, we have written part of the numerical integration of Eq.(2.4a) in C language and compiled the part using MATLAB's built-in *mex* function and the Microsoft Visual C++ 2015 compiler (Altman, 2014).

2.4.2 Verification and examples

For isotropic materials, results (Fig.2.5) obtained from the package for rigid spheroids in an isotropic matrix reproduce perfect “Jeffery orbits” obtained from analytical solutions (e.g., Jeffery, 1922; Freeman, 1985; Ježek, 1994; Jiang, 2007a). In Fig.2.5, the rotation paths follow Jeffery orbits even when the shear strain reaches 100. For deformable ellipsoids in an isotropic matrix, results from the package are identical to those obtained from the MathCad worksheets of Jiang (2007b, 2012) in which the Eshelby tensors are calculated from the closed-form expressions.

Figure 2.5 An execution of SGLRGD. The rotation paths for the rigid ellipsoids embedded in an isotropic matrix in simple shearing flows plotting on equal-area projections. Red and green color symbols are, respectively, hemispheres associated with positive x_3 and negative x_3 half-spaces. ‘×’ represents the initial state, and ‘*’ represents the final state. Input parameters are $\mathbf{L} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$ for

simple shearing flow field, $\text{ang} = \begin{pmatrix} 100 \\ 60 \\ 30 \end{pmatrix}$, $\text{tincr} = 0.01$, $\text{steps} = 10000$, (a) is the

rotation path of a prolate ellipsoid $\mathbf{a} = \begin{pmatrix} 5 \\ 1 \\ 1 \end{pmatrix}$, and (b) is the rotation path of an

oblate ellipsoid $\mathbf{a} = \begin{pmatrix} 5 \\ 5 \\ 1 \end{pmatrix}$. Perfect Jeffery orbits are produced in excellent

agreement with analytic solutions of Jeffery (1922), Freeman (1985), Ježek (1994), Jiang (2007a).

For inclusions in an incompressible anisotropic material, to our knowledge, there is no 3D analytical solution available. To verify the package for anisotropic materials, we compare our numerical results for an extremely elongate ellipsoid (to approximate an elliptical cylinder) in a plane-straining flow with the 2D analytical solutions of Fletcher (2009) for an ellipse in a homogeneous incompressible viscous matrix with planar anisotropy under plane-straining flows. The imposed velocity gradient tensor \mathbf{L} is:

$$\mathbf{L} = \begin{pmatrix} \varepsilon & \gamma & 0 \\ 0 & -\varepsilon & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad (2.11)$$

where ε and γ are the pure shearing strain rate and simple shear rate, respectively. We use an extremely elongate ellipsoid with its a_3 semi-axis parallel to the vorticity (the x_3 axis) of the flow (Fig.2.6a) to approximate an elliptic cylinder in 2D flows. The specific anisotropic matrix considered by Fletcher (2004, 2009) is one with a planar anisotropy. The corresponding viscous stiffness tensor \mathbf{C} with the anisotropy plane (i.e., “foliation”) normal to the x_2 axis (Figs.2.6) can be written in a block matrix form (see Jiang, 2016) as follows:

$$C_{ijkl} = 2\eta_n \begin{pmatrix} J_{11kl}^D & \frac{1}{m} J_{12kl}^D & J_{13kl}^D \\ \frac{1}{m} J_{12kl}^D & J_{22kl}^D & \frac{1}{m} J_{23kl}^D \\ J_{13kl}^D & \frac{1}{m} J_{23kl}^D & J_{33kl}^D \end{pmatrix} \quad (2.12)$$

(a)

(b)

Figure 2.6 An isotropic ellipsoid embedded in a matrix with planar anisotropy.

The matrix rheology is defined by η_n and η_s . $m = \eta_n / \eta_s$ indicates the strength of the anisotropy. The imposed plane-straining general shear flow (ϵ is the pure shearing strain rate and γ is simple shear rate) is defined in the x (white) coordinate system. The ellipsoid's principal axes define x' (black) coordinate system at angle φ .

where $\mathbf{J}^{\mathbf{D}}$ is the same as defined in Eqs.(2.1), and η_n is the foliation-normal viscosity measuring the resistance of the matrix to pure shearing along and perpendicular to the anisotropy plane, $m = \eta_n / \eta_s$ with η_s being the foliation-parallel viscosity measuring the resistance to shearing parallel to the anisotropy plane (Fig.2.6b). The parameter m indicates the strength of the anisotropy (Treagus, 2002; Fletcher 2004, 2009; Chen et al., 2014).

The analytic solutions in Fletcher (2009, his Eqs.14&15) can be rewritten in the following forms (Jiang, 2016):

$$\tilde{\varepsilon}_{11} = \frac{2\sqrt{m}R}{R^2 + 2r\sqrt{m}R + 1} \left[-r \left(\varepsilon \cos 2\varphi + \frac{\gamma}{2} \sin 2\varphi \right) + \left(\varepsilon \cos 2\varphi + \frac{\gamma}{2m} \sin 2\varphi \right) \right] \quad (2.13a)$$

$$\tilde{\varepsilon}_{12} = \frac{\sqrt{m}(R^2 + 1)}{r\sqrt{m}(R^2 + 1) + 2R} \left[-r \left(-\varepsilon \sin 2\varphi + \frac{\gamma}{2} \cos 2\varphi \right) + \left(-\varepsilon \sin 2\varphi + \frac{\gamma}{2m} \cos 2\varphi \right) \right] \quad (2.13b)$$

$$\tilde{w}_{12} = \frac{R^2 - 1}{R^2 + 1} \tilde{\varepsilon}_{12} = \frac{\sqrt{m}(R^2 - 1)}{r\sqrt{m}(R^2 + 1) + 2R} \left[-r \left(-\varepsilon \sin 2\varphi + \frac{\gamma}{2} \cos 2\varphi \right) + \left(-\varepsilon \sin 2\varphi + \frac{\gamma}{2m} \cos 2\varphi \right) \right] \quad (2.13c)$$

where the tilde above a quantity stands for the difference in the quantity between the inclusion and matrix (e.g., $\tilde{w}_{12} = w_{12} - W_{12}$), $R = a_1 / a_2$ indicates the shape of an ellipse, r is the ratio of the inclusion viscosity to the matrix η_n , and φ is the angle between the

ellipse a_1 semi-axis and the anisotropy plane (Fig.2.6b). For a rigid inclusion (i.e., $r \rightarrow \infty$), Eq.(2.13c) becomes (Eq.17 in Fletcher (2009))

$$\tilde{w}_{12rigid} = -\frac{R^2 - 1}{R^2 + 1} \left(-\varepsilon \sin 2\varphi + \frac{\gamma}{2} \cos 2\varphi \right) \quad (2.14)$$

Fig.2.7 presents the results for a rigid inclusion ($R = 10$) in plane-strain general shear ($\varepsilon = 0.5$ and $\gamma = 1$) obtained from the MATLAB package and those calculated directly using Eq.(2.14). In Fig.2.7, a_3 is set to 5, 15, 50 and 100. When $a_3 = 100$, the results from the package agree with the 2D analytical results. Fig.2.8 presents the results for a deformable inclusion ($R = 5$, $r = 10$, and $m = 25$) in plane-strain general shear ($\varepsilon = 0.5$ and $\gamma = 1$). In Fig.2.8, $a_3 = 100$, the numerical results agree with the analytical ones perfectly.

The package applies to 3D flows of course. Figs.2.9 and 2.10 are examples of a rigid triaxial ellipsoid (5:3:1) embedded in a planar anisotropic matrix ($m = 25$) and a deformable ($r = 2$) triaxial ellipsoid (5:3:1) embedded in a planar anisotropic matrix ($m = 10$), respectively. Detailed inputs are in figure captions.

Figure 2.7 Comparison of the vorticity difference \tilde{w}_{12} of a rigid inclusion ($R = 10$) in plane-strain general shear ($\varepsilon = 0.5$ and $\gamma = 1$) calculated from the MATLAB package (green markers: $a_3 = 5$, magenta markers: $a_3 = 15$, cyan markers: $a_3 = 50$, red markers: $a_3 = 100$) with the results calculated with Fletcher's analytical solutions (dashed line). The figure shows that the result from the package converges to the 2D analytical result with the increase of a_3 . When $a_3 = 100$, the result from the package is undistinguishable from the 2D analytical result.

Figure 2.8 Comparison of the strain rates differences, $\tilde{\varepsilon}_{11}$ and $\tilde{\varepsilon}_{12}$, and the vorticity difference \tilde{w}_{12} of a deformable inclusion ($R = 5$, $r = 10$, and $m = 25$) in plane-strain general shear ($\varepsilon = 0.5$ and $\gamma = 1$) calculated from the MATLAB package (cross markers, $a_3 = 100$) with the results calculated with Fletcher's analytical solutions (dashed lines).

Figure 2.9 An example of using SGLRGD. Rotational paths of three semi-axes on equal-area projections. Red and green color symbols are, respectively, hemispheres associated with positive x_3 and negative x_3 half-spaces. 'x' represents the initial state, and '*' represents the final state.

Input parameters are $L = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$, for simple shearing flow field,

$\text{ang} = \begin{pmatrix} 100 \\ 60 \\ 30 \end{pmatrix}$, $\mathbf{a} = \begin{pmatrix} 5 \\ 3 \\ 1 \end{pmatrix}$, $\text{tincr} = 0.01$, $\text{steps} = 1000$, $m=25$.

2.4.3 Structure of the package

The package contains the following four MATLAB functions that one can run directly:

SGLRGD is for the simulation of a single rigid inclusion;

SGLDEF is for the simulation of a single deformable inclusion;

MLTRGD is for the simulation of multiple non-interacting rigid inclusions;

MLTDEF is for the simulation of multiple non-interacting deformable inclusions.

The folder *Routines* contains all the functions called in the above four executable functions. The optimal scheme to compute the 4th-order Green interaction tensor \mathbf{T} is named “*TGreen.m*”. “*partTGL.mexw64*” and “*partTLeb.mexw64*” are two MEX (MATLAB Executable) files, written in C and compiled using the MATLAB's built-in *mex* function and the Microsoft Visual C++ 2015 compiler on the Win64 platform using MATLAB version R2016a. The subfolder, *C codes*, contains C source codes (“*partTGL.c*” and “*partTLeb.c*”) for “*partTGL.mexw64*” and “*partTLeb.mexw64*”. The subfolder, *Lebedev*, is taken from the library of Saff and Kuijlaars (1997) to generate nodes and weights following the Lebedev quadrature rules.

The validations in this paper are stored in the *Validations* folder (i.e., *RGDval* and *DEFval*). One can run the two functions in the folder to obtain Figs.2.7 and 2.8.

For power-law viscous deformable inclusions (i.e., *SGLDEF* and *MLTDEF*), $\boldsymbol{\varepsilon} = \left[\mathbf{J}^D + \mathbf{S} : (n_M \mathbf{C}_E^{(\text{sec})} : \mathbf{C}_M^{(\text{sec})-1} - \mathbf{J}^D) \right]^{-1} : \left[\mathbf{J}^D + (n_M - 1)\mathbf{S} \right] : \mathbf{E}$ (Eq.23 in Jiang, 2014). The linearized viscous stiffness is not a material constant but depends on the current state of deviatoric stresses (or strain rates). If the ellipsoidal inclusion is isotropic, we input an initial effective viscosity (η_{eff}^E) defined at a given reference strain rate for the ellipsoid and use calculated $\boldsymbol{\varepsilon}$ to update the effective viscosity (Ranalli, 1995; Mancktelow, 2011; Jiang, 2013) iteratively until the new calculated effective viscosity converges within the prescribed tolerance (“*Ed.m*” in *Routines*). If the inclusion is anisotropic, the input of a full constitutive relation (e.g., $\varepsilon_{ij} = g_{ij}(\sigma'_{kl})$) for the inclusion is necessary to update the linearized viscous stiffness, and the equation $\boldsymbol{\varepsilon} = \left[\hat{\mathbf{C}}_M : (\mathbf{S}^{-1} - \mathbf{J}^D) + \hat{\mathbf{C}}_E \right]^{-1} : \hat{\mathbf{C}}_M : \mathbf{S}^{-1} : \mathbf{E} + \left[\hat{\mathbf{C}}_M : (\mathbf{S}^{-1} - \mathbf{J}^D) + \hat{\mathbf{C}}_E \right]^{-1} : (\boldsymbol{\Sigma}^0 - \boldsymbol{\sigma}^0)$ (Eq.17 in Jiang, 2014) can be used to calculate $\boldsymbol{\varepsilon}$.

For the detailed implementation of the package, one can refer to Appendix B, the “*ReadMe.txt*” and comment lines in the package.

2.5 Summary and discussion

In this work, we have proposed an optimal numerical integration scheme (Fig.2.4) to efficiently evaluate Eshelby tensors. We have implemented this scheme in a MATLAB package to simulate the evolution of a single ellipsoid or dilute multiple ellipsoids embedding in a viscous material. The MATLAB package is applicable for general anisotropic incompressible viscous materials.

The optimal scheme in Fig.2.4 captures the effect of the inclusion’s shape on the integrand in Eq.(2.4a). This scheme is based on isotropic matrix rheology. Clearly,

the computational effort to evaluate Eq.(2.4a) is also affected by the viscous stiffness tensor of the matrix (\mathbf{C}_M) if the material is anisotropic. There is an infinite number of possible anisotropic \mathbf{C}_M , and it is impossible to address their effect on computation time generally. In principle, the anisotropic effect of \mathbf{C}_M can be investigated case by case and a diagram similar to Fig.2.4 can be constructed once a specific type of \mathbf{C}_M is given. We have applied our optimal scheme (based on the isotropic matrix) to a planar anisotropic matrix in the validation section. For a very high degree ($m = 25$) of anisotropy, our numerical results agree with the analytical solutions (Fig.2.8) perfectly. Based on this, we tentatively conclude that the effect of anisotropic \mathbf{C}_M on the computational time of Eq.(2.4a) is insignificant compared to an ellipsoid shape. This may suggest that the optimal scheme in Fig.2.4 is generally applicable to general anisotropic matrices. Nevertheless, planar anisotropy is among the most common in natural deformed rocks.

To further speed up the MATLAB package, one can call BLAS (Basic Linear Algebra Subprograms) to perform matrix operations in the C source codes, and use open source libraries (e.g., MPI (Message Passing Interface)) or GPU programming (e.g., CUDA (Compute Unified Device Architecture)) to make the calculations on each node carried out simultaneously during the computation.

Chapter 3: Deformation of the Shangdan Tectonic Zone in the Eastern Qinling Orogenic Belt

3.1 Introduction

The Qinling Orogenic Belt (QOB) extends more than ~1000km from west to east across central China and links Dabie Mountains in the east and Qilian and Kunlun Mountains in the west (Fig.3.1a, Dong et al., 2011a). It is commonly accepted that the QOB was as a result of episodic subductions and collisions of microcontinental fragments prior to the Triassic continent-continent collision between the North China Block (NCB) and the South China Block (SCB) (e.g., Zhang et al., 2001; Dong et al., 2011a,b; Wu and Zheng, 2013; Dong and Santosh, 2016). The Shangdan suture separates the QOB into the North Qinling Belt (NQB) and the South Qinling Belt (SQB) and is defined by the discontinuously exposed Danfeng Complex that consists of ophiolitic mélangé (Fig.3.1b, Zhang et al., 2001; Dong et al., 2011a,b; Dong and Santosh, 2016). The deformation documented in the Shangdan suture and its adjacent areas is important to investigate the tectonic boundary conditions during the deformation and thus to understand the tectonic evolution of the QOB.

Along the Shangdan suture, sub-vertical foliations and sub-horizontal stretching lineations with sinistral shear-sense indicators have been observed in mylonites (Mattauer et al., 1985; Xu et al., 1986; Zhang et al., 1989; Reischmann et al., 1990; Wang et al., 2005), and the set of fabrics indicates a conspicuous sinistral strike-slip deformation along the Shangdan tectonic zone. Mattauer et al. (1985)

proposed that the displacement of the strike-slip deformation is at least 100km. However, the age of this deformation is still in dispute. Mattauer et al. (1985) and Xu et al. (1986) obtained a biotite ^{39}Ar - ^{40}Ar plateau age of 314 ± 6 Ma in mica schist with subvertical foliation and E-W stretching lineation along the Shangdan zone, and they (Mattauer et al., 1985; Xu et al., 1986) interpreted this age as the start of the sinistral strike-slip deformation. Wang et al. (2005) correlated this deformation along the Shangdan suture to a deformation zone (the Zhuxia zone) in the Qinling Complex and interpreted the biotite ^{39}Ar - ^{40}Ar plateau age of 314 ± 6 Ma in Mattauer et al. (1985) as the late stage of the sinistral strike-slip deformation. Reischmann et al. (1990) obtained a U-Pb zircon age of 211 ± 8 Ma from a mylonitic pluton in the Shagou shear zone, a segment of the Shangdan tectonic zone. Along with a Sm/Nd garnet-whole rock age of 126 ± 9 Ma, Reischmann et al. (1990) proposed that the sinistral ductile deformation happened between 211Ma and 126Ma. According to a Rb-Sr whole-rock isochron age of 219Ma and a U-Pb zircon age of 211 ± 8 Ma from a mylonite along the Shangdan tectonic zone, Zhang et al. (1989) proposed that the ductile deformation along Shangdan tectonic zone was at the late Triassic resulting from the ultimate convergence of the NCB and the SCB.

Figure 3.1 Geological maps to show the Qinling orogenic belt and the eastern Qinling orogenic belt. (a).Geological map showing the location and composition of the Qinling orogenic belt and its adjacent areas (Dong and Santosh, 2016). The map in the upper right corner shows the location of the Qinling orogenic belt in China. (b). Geological map of the eastern Qinling belt showing the major geological units and field work areas (the Heihe area and the Danfeng area) (Dong et al., 2013; Liao et al., 2017). SSF: Shanyang-Fengzhen fault.

The Paleozoic Shangdan suture contain ultramafic and mafic rocks that have characteristics of N-MORB, E-MORB, boninite and island-arc basalts were formed during 534-500Ma (Dong et al., 2011b; Liu et al., 2016). Cambrian-Ordovician radiolarians and conodonts were found in the Danfeng Complex (Cui et al., 1995; Ding et al. 2004). Subduction-related volcanic and sedimentary rocks are in the range of ca.530-470Ma (Dong and Santosh, 2016). Although the exact deformation time along the Shangdan suture and its vicinity is still unclear, it is either during the early Mesozoic in response to the collision between the SQB and the SCB or during the Paleozoic after the assemblage of the SQB and the NQB. In both processes, the predominant strike-slip deformation along the Shangdan tectonic zone was not compatible with the compressional tectonic boundary during the collisional process.

An orogenic belt, especially as the QOB that contains different geological units and has experienced a long time of evolution (thus involved numerous structures, fluids, new minerals, etc.), is a very complicated region and consists of omnipresent rheological heterogeneities. Ubiquitous rheological heterogeneities throughout a deformation zone can cause significant flow-field partitioning (Lister and Williams, 1983), and hence the deformation demonstrated in different geological domains may show different characteristics over a wide range of observational scales (e.g., outcrops, thin-sections). Thereupon, in a tectonic-scale transpressional zone, such as the Shangdan tectonic zone, small-scale structural features (e.g., stretching lineations, shear-sense indicators) on outcrops or in thin sections are directly related to the ‘local’ partitioned flow fields but not to the ‘bulk’ tectonic-scale boundary conditions (Jiang, 2014). Recently, Jiang and Bentley (2012) and Jiang (2013, 2014) have proposed a

robust multi-scale approach to handle flow-field partitioning that has been introduced in Chapter 1 and Chapter 2, and we apply this approach to understand the deformation of the Shangdan tectonic zone.

In this work, we conduct detailed structural analysis along the Shangdan suture and its adjacent areas, collectively referred to as the Shangdan tectonic zone (SDTZ) in this paper, to investigate the deformation history and deformation time of the SDTZ along with previous geochronological works. In addition, we apply the recently developed multiscale approach (Jiang and Bentley, 2012; Jiang, 2013, 2014) to the study area and connect small-scale fabrics in distinct rheological domains to large-scale tectonic synthesis and to infer the tectonic-scale boundary conditions of the SDTZ.

3.2 The Shangdan tectonic zone

3.2.1 Geological setting

The Shangdan suture zone divides the QOB into the NQB and the SQB. One can refer to Dong and Santosh (2016) for the detailed geological descriptions of each geological unit in the QOB. Here, only the geological units that are involved in the field work areas are introduced. The field work is conducted in two regions along the SDTZ (i.e., the Heihe area and the Danfeng area, Fig.3.1b, Fig.3.2, Fig.3.8).

Figure 3.2 Geological map showing the geological units in the Heihe area (modified from 1:200000 regional geological map). The Shaliangzi township is on the upper left corner of the map.

In Heihe, the field work is conducted in a sedimentary unit (the yellow area in Fig.3.2). The unit is characterized by the metamorphosed conglomerate, sandstone, shale and carbonate from bottom to top (Meng et al.,1994; Yu and Meng, 1995; Dong et al., 2013). This unit is interpreted as a fore-arc sedimentary prism according to the investigation of the conglomerates outcropping as two intercalations within sandstones and volcanic rocks (Meng et al., 1994, 1997; Yu and Meng, 1995). The depositional age of the sedimentary unit is bracketed in the range of ca.455-435Ma by the youngest detrital zircon (ca.455Ma) and the magmatic zircons ($435\pm 7\text{Ma}$, $\text{MSWD}=4.1$) from a mafic dyke that intruded in the sedimentary unit (Dong et al., 2013). The comparison of the detrital zircon age populations from the sedimentary unit with the known ages from the NQB and the SQB suggests that the sedimentary provenance is attributed to the NQB (Dong et al., 2013).

In Danfeng, the field work is mainly conducted in the Danfeng Complex, the Wuguan Complex and the Liuling Group (Fig.3.8). *Danfeng Complex* is discontinuously exposed and composed of ophiolitic assemblages, arc-related volcanic rocks and sedimentary rocks (Zhang et al., 1995; Zhang et al., 2001; Dong et al., 2011a, b). The rocks underwent greenschist to lower amphibolite metamorphic facies, and the formation age of these rocks was constrained by zircon U-Pb ages of ca.534-470Ma from mafic rocks of the ophiolitic assemblages and subduction-related rocks (Dong and Santosh, 2016 and reference therein). The Danfeng Complex marks the Shangdan suture. *Wuguan Complex* is composed of quartz schists, marbles and amphibolites (Pei, 1997). The depositional age of the Wuguan Complex is in the range of ca.389-330 Ma according to the detrital zircon age analyses (Yan et al., 2016). *Liuling Group* consists of the several kilometers thick turbidite sequences and has been further divided into the Niuerchuan formation, Chigou formation, Qingshiya formation, Xiadonggou formation, and Tongyusi formation from the lower to the upper strata (Zhang et al., 2001). According to the youngest detrital zircon (400Ma) data (Dong et al., 2013) and the crystallization age (373.8Ma) of a pegmatitic dyke, the depositional age of the Liuling Group is constrained to 373.8-400Ma (Shi, 2016).

3.2.2 Structural geometry

3.2.2.1 The Heihe area

A highly deformed meta-conglomerate is found at the Shaliangzi township on Fig.3.2, and the rest of the deformed rocks are mainly meta-sandstone, meta-pelite and marble.

Figure 3.3 Photos showing the deformed conglomerate at the Shaliangzi township. The conglomerate is clast-supported and contains granitoid pebbles, quartzite pebbles, amphibolite pebbles and marble pebbles.

Figure 3.4 A diagram showing the concept of a fabric ellipsoid. (a). On an arbitrary planer section, a deformed pebble is exposed as an ellipse. $R_f = \frac{a}{b}$ ($R_f \geq 1$) represents the shape, and φ ($0^\circ \leq \varphi < 180^\circ$) describes the orientation. (b). On an outcrop, 2D fabric data are measured from planar sections, and a best-fit ellipse from each section can be calculated (modified after Giorgis and Tikoff, 2004). (c). A best-fit 3D fabric ellipsoid can be obtained from 2D best-fit ellipses.

The apparent thickness of the conglomerate is up to 50m (Dong et al., 2013), and the matrix of the conglomerate is greywacke and recorded greenschist to amphibolite metamorphic facies indicated by the existence of new grown amphibole and biotite. The deformed conglomerate is clast-support, and the percentages of clast and matrix are 80% and 20%, respectively. The deformed conglomerate contains

polymictic pebbles including granitoid (~40%), quartzite (~30%), amphibolite (~20%) and marble (~10%), and sizes of pebbles are in the range between 3cm and 30cm (Fig.3.3).

Deformed conglomerates are important strain markers compared with other strain markers (such as deformed fossils), as they are widely distributed in deformed rocks and easy to be recognized after intense deformation and high-grade metamorphism and able to indicate the total strain since their deposition (Ramsey, 1967; Lisle, 1979). One way to extract the information that deformed conglomerates hold is to collect fabric data (shape and orientation of deformed pebbles) on planar sections and summarize the results into a fabric ellipsoid (Fig.3.4). On a planar section,

the shape of a deformed pebble can be represented by $R_f = \frac{\text{long axis}}{\text{short axis}}$ (a and b in

Fig.3.4a) and the pitch of the long axis (φ in Fig.3.4a) can represent the orientation of the deformed pebble. According to the solutions in Robin (2002), after measuring sufficient fabric data of deformed pebbles on a planar section, a best-fit sectional ellipse is found (Fig.3.4b). After best-fit sectional ellipses are obtained from N ($N \geq 3$) planar sections, together with the orientations of the planar sections, a best-fit 3D fabric ellipsoid can be obtained (Fig.3.4c, Robin, 2002).

The aspect ratio (R_f) and the orientation of the long axis (φ) of each pebble on 15 field exposed sections are measured. Best-fit fabric ellipsoids of granitoid, quartzite, amphibolite and marble pebbles are obtained. The measured data are in Appendix D. The shape of the fabric ellipsoids is plotted in the Flinn diagram (Fig.3.5a)

to investigate the deformation of the conglomerate. Four fabric ellipsoids are all plotted in constrictional deformation on the Flinn diagram. According to the distance from the origin to the points, the strain magnitudes reflected from four fabric ellipsoids are marble > quartzite > amphibolite \approx granite, and thus the competence sequence of the four types of pebbles is in reverse. The longest axis of the fabric ellipsoid is comparable with the stretching lineations, and the longest axes of the fabric ellipsoids from four types of pebbles are plotted on a lower-hemisphere equal-area projection (Fig.3.5b). Although four types of pebbles show distinct competence, the longest axes of their fabric ellipsoids are all sub-horizontally. The orientation is coincident with the stretching lineations (Fig.3.7) throughout the Heihe area.

Figure 3.5 Fabric data from the deformed conglomerate. (a). the Flinn diagram of the amphibolite, granitoid, marble and quartzite fabric ellipsoids. a_1, a_2, a_3 are three semi-axes of a fabric ellipsoid ($a_1 > a_2 > a_3$). (b). Lower-hemisphere equal-area projection of the longest axes of the four fabric ellipsoids.

The rest of this region are highly transposed metamorphic tectonites (meta-sandstone and meta-pelite). Sub-vertical foliations and horizontal lineations are developed in S>L tectonites. Foliations are mainly slaty cleavage in meta-pelite and schistosity in meta-sandstone, and the rocks show a very strong preferred orientation under microscope. Lineations are mineral stretching lineations defined by elongate mineral aggregates on outcrops, and the aggregate is mainly composed of quartz and mica. Shear sense indicators (including S-C-C', S-C fabrics and rotated porphyroclasts) are well developed on sub-horizontal sections on outcrops and in thin sections showing a sinistral sense of shear (Fig.3.6).

Figure 3.6 Photos showing shear-sense indicators in the Maanqiao shear zone (southern part of the fore-arc sedimentary unit). (a) and (b) present S-C fabric in metamorphic sandstones on the outcrop, and sense of shear is sinistral. (c) and (d) show tails of deformed quartzite pebbles in outcrop, reflecting sinistral shear. The photos are taken on sub-horizontal planes.

Figure 3.7 A conceptual block diagram summarizing the fabrics in the Heihe area. The right corner plot is a lower-hemisphere equal area projection of stretching lineations and poles to foliation throughout the tectonites in the Heihe area. Green dots are stretching lineations, and red triangles are poles to transposition foliations.

In brief, the fabric data in the Heihe area can be summarized as a conceptual block diagram in Fig.3.7. The structural geometry in Fig.3.7 shows a sinistral strike-slip dominated transpressional deformation (Lin et al., 1998; Jiang and Williams, 1998). The constrictional deformation shown in the deformed conglomerate can be explained by the heterogeneity of the deformed rocks. Generally, in a strong domain, under a transpressional deformation, the deformed rocks tend to show a constrictional

deformation (Freeman and Lisle, 1986; Chen, 2014), so the deformed conglomerate is more competent than the surrounding matrix (i.e., the meta-sandstone and meta-pelite).

3.2.2.2 The Danfeng area

In the Danfeng area (Fig.3.8), four outcrop-scale high-strain zones are observed along the SDTZ, and two generations of deformation can be recognized in the Liuling Group.

Figure 3.8 Geological map showing the geological units in the Danfeng area (modified from 1:200000 regional geological map and Dong et al., 2013).

Outcrop-scale high strain zones are observed along the SDTZ in the Wuguan Complex and the Danfeng Complex. Sub-vertical foliations and horizontal stretching lineations (Fig.3.9e) are developed in mylonites and highly transposed metamorphic tectonites. Shear-sense indicators are well developed on sub-horizontal sections on outcrops and in thin sections showing a sinistral sense of shear (Figs.3.9a-d). Two

generations of deformation can be observed on the outcrops in Qingyouhe and Mianyuzui. As the second generation is at the same scale of the first generation and they both show the same geometric features, the two generations of deformation are interpreted as the different stages of one progressive deformation event (Fig.3.10).

Field geometries indicate two generations of deformation in the Liuling Group. These two generations of deformation in the Liuling Group are referred to as D_1 deformation and D_2 deformation in this paper. The significant structures of D_1 deformation are isoclinal folds (F_1) that are associated with the occurrence of transposition foliation or crenulation cleavage (S_1) and mineral lineations (Fig.3.11). F_1 folds can be recognized from the geological map (Fig. 3.8) of the Liuling Group. D_2 deformation is represented by recumbent (F_2) folds with crenulation cleavage (S_2) parallel to F_2 axial planes (Fig.3.12). L-tectonite, which is generated by D_2 deformation, is defined by F_2 hinge lines (Fig.3.12). The distinctive D_2 structures are observed in the Liuling Group only. The overprinting relationship between D_1 fabrics and D_2 fabrics can be recognized on the outcrops. The structures developed by D_2 deformation are heterogeneous spatially. D_2 deformation can be well recognized in the southern part of the Maoligang and the Zhulinguan areas. Only a few D_2 fabrics can be observed in the southernmost of the Lishangou and the Laopenggou areas. Namely, D_2 deformation becomes weaker northward where D_1 deformation is well preserved.

Figure 3.9 Photos and fabric data from the high-strain zones. (a-d) Photos showing shear-sense indicators on outcrops in the high-strain zones. All photos are taken on sub-horizontal surfaces. (e) Lower-hemisphere equal-area projection of stretching lineations and transposition foliations in high-strain zones. Green dots are stretching lineations, and red triangles are poles to transposition foliations. The black great circle is the average of the foliations, and

the light blue star is the average of the lineations (close to horizontal and covered by green dots).

3.3 Theoretical modeling

Figure 3.13 A conceptual block diagram (not to scale) to illustrate the following idea: the sinistral strike-slip deformation is concentrated in a weak domain along the SDTZ, together with the F₁ Folding in the Liuling Group, resulting from the oblique convergence between the SCB and the NCB.

If D₂ deformation in Liuling group is removed, the fabric data in the Heihe area, fabrics in high-strain zones and the D₁ fabrics in the Liuling Group can be summarized into a conceptual block diagram (Fig.3.13). We think that this set of fabrics (sinistral shearing along the SDTZ and F₁ Folding) was mainly produced by the oblique convergence between the SCB and the NCB in the Triassic. The detailed discussion on the deformation time is in the next section. As the Shangdan suture was developed during Paleozoic, the high strain zone along the SDTZ was an existing weak zone during the Triassic.

The theoretical modeling is used to test the above idea. The tectonic-scale boundary condition is an oblique convergence with the convergence angle α

(Fig.3.14a). The SDTZ is considered as a weak Eshelby inclusion in the transpressional zone and the Liuling group is the matrix that is near the inclusion (Fig.3.14c). Different far-field tectonic boundary conditions (i.e., α) are tested, and simulated fabrics are compared with the measured results to further constrain the tectonic boundary condition.

The ‘SGLDEF’ MATLAB program in Chapter 2 is used to model the deformation inside the inclusion and in the bulk matrix.

3.3.1 Numerical model setup

The tectonic boundary condition is constrained by plate motions. Here, we consider an oblique convergence between the SCB and the NCB. The convergence angle is, and a monoclinic transpressional deformation is modeled (Fig.3.14a). The velocity gradient tensor is

$$\mathbf{L} = \begin{bmatrix} 0 & -\cos \alpha & 0 \\ 0 & -\sin \alpha & 0 \\ 0 & 0 & \sin \alpha \end{bmatrix} \varepsilon_v$$

where α is the convergence angle and ε_v is the average deformation rate of the zone. Since we consider the fabric is the final product of the progressive deformation and the absolute rate will not affect the final product, the average deformation rate ε_v is simply set to 1. The time increment for computation is $\delta t = 0.01$ to ensure that every step of the computation corresponds to an infinitesimal increment of deformation.

The SDTZ is a deformation concentration zone and modeled as a weak Eshelby inclusion (Fig.3.14c). The shape of the zone is represented by an ellipsoid. Three semi-

axes of the ellipsoid are set to 50:5:1. The longest axis represents the length of the zone, the mediate axis represents the depth of the zone, and the shortest axis is the width of the zone. The longest axis of the ellipsoid or the strike of the zone is parallel to the tectonic boundary. As the Shangdan suture was produced by the northward subduction of the Shangdan oceanic plate under the NQB (Dong and Santosh, 2016), before the deformation in the Triassic, the weak zone was dipping to the north, and the dip angle is β . According to current subduction zones, β is tested from 90° to 50° (Zoback et al., 1987; Davey et al., 1995; Norris and Cooper, 2000).

All materials considered in the model are assumed to be power-law viscous with stress exponent equals to 3. The choices of the viscosity of the materials are rather arbitrary based on an incomplete understanding of rheological contrasts in rocks (e.g., Treagus, 2002; Czeck et al., 2009). The relative effective viscosity of the high-strain zone is set to 0.1 defined at the macroscale strain-rate state to represent a weak domain.

To estimate the foliation and lineations inside the high-strain zone and in the matrix, we assume that the high-strain zone is a homogeneous domain and so as the matrix. We use the position gradient tensor, \mathbf{F} , to represent the deformation of a continuous body (Jiang, 2010). For the bulk deformation, $\mathbf{F}(t) = \exp(\mathbf{L}t)$, where t is the deformation time (Eq.35 in Jiang, 2010). For the deformation inside the high-strain zone where the deformation is not steady, \mathbf{F} is updated after every step. Principal stretch axes can be calculated from \mathbf{F} (Truesdell, 1991). The maximum principal stretch axis represents stretching lineations, and the minimum principal stretch axis represents poles to the foliations (Lin et al., 1998; Jiang and Williams, 1998).

$STEPS = 300$ is taken for all simulations to illustrate the evolution of lineations and foliations inside the high-strain zone and in the bulk matrix.

Figure 3.14 Numerical modeling diagram. (a). Transpression model for the macroscale deformation of the SDTZ. As the boundary condition is produced by the plate motion and the SDTZ is far from the plate margin, the deformation resulted from the oblique convergence with a convergence angle α in the transpression zone is monoclinic. Therefore, in the modeling, a vertical instead of an inclined transpression zone is considered, and different convergence angles (α) are simulated. (b). The coordinate system for the equal-area projections of the simulation results. (c). The SDTZ is modeled as an Eshelby ellipsoid inside the transpression zone. Different initial dip angles (β) of the SDTZ are tested.

3.3.2 Modeling results

We systematically test different α and β , and output the evolution of foliation and lineation inside the high-strain zone and in the bulk matrix. The comparison between the simulation results and the field measurements is used to constrain the

tectonic-scale deformation boundary conditions. The evolution of the orientations of stretching lineations (the maximum strain axis is interpreted as the stretching lineation) inside the high-strain zone (dark blue) and in the bulk matrix (light blue) for different convergence angle and dip angles are presented in Fig.3.15. The evolution of the transposition foliation (the minimum strain axis is interpreted as the pole to the transposition foliation) is plotted in Fig.3.16.

All results in Fig.3.16 represents the evolution of the foliations inside the high-strain zone and in the bulk matrix. The transposition foliations show similar patterns, and hence the transposition foliations are not sensitive to the change of convergence angles and dip angles. This is consistent with single-scale kinematic transpression models (e.g., Jiang and Williams, 1998; Jiang, 2007) and the multiscale model that considers fabric elements to define the transposition foliation (Jiang, 2014). The transposition foliations in the bulk matrix and in the high-strain zone tend to rotate to the transpressional deformation zone boundary, and the transposition foliation in the high-strain zone rotates faster. This phenomenon may because that there is more simple-shearing component partitioned in the high-strain zone (Xiang and Jiang, 2013) and the strains accumulated faster in the high-strain zone than in the bulk matrix. For different dip angles especially for small convergence angles, the intersection angle between the transposition foliation inside the high-strain zone and the transposition foliation in the bulk matrix is slightly different, but this difference is too small to be observed in the field.

The evolution of lineations is extremely sensitive to the change of the dip angles and convergence angles.

In simple shearing flow or flow with a small convergence angle ($\alpha = 0^\circ$ or 10°), the evolution of the lineation inside the high-strain zone and in the bulk matrix is along the strike of the foliations. This is consistent with single-scale kinematic transpression models (e.g., Jiang and Williams, 1998).

For vertical weak domains ($\beta = 90^\circ$), the lineation inside the zone is numb to the change of the convergence angle: for $\alpha = 0^\circ \sim 50^\circ$, the lineation in the vertical weak zones is invariably horizontal.

For intermediate and slightly large convergence angles ($\alpha = 20^\circ \sim 50^\circ$), the dip of the weak domain plays a key role to affect the evolution of the lineation inside the domain. For steeply dipping domains ($\beta = 70^\circ \sim 80^\circ$) under intermediate convergence angles ($\alpha = 20^\circ \sim 40^\circ$), although the bulk lineations are down-dip, lineations inside the weak domain are still horizontal or sub-horizontal, while for gently dipping domains ($\beta = 50^\circ \sim 60^\circ$), the lineations are oblique. In the case of $\alpha = 50^\circ$ and $\beta = 50^\circ$, the lineation inside the weak domain is close to the lineation in the bulk matrix. It seems that the decrease of the dip angle and the increase of the convergence angle show the similar effects on the development of the lineation inside the weak domain. They both tend to produce steep lineations inside the weak domain.

Figure 3.15 Simulation results of lineations for different convergence angles (α) and dip angles (β). The projection is x_3 – *positive* hemisphere equal-area projection. Light blue dots are the evolution of the lineation in the bulk matrix, and dark blue dots are the evolution of the lineation in the high-strain zone. ‘x’ is the starting dot, and ‘*’ is the end dot.

Figure 3.16 Simulation results of poles to foliations for different convergence angles (α) and dip angles (β).

3.3.3 Comparison of the simulation results with the field data

The field data that are rotated to the model coordinate system are shown in Fig.3.17. The fabrics are characterized by the lineations along the strike of the foliations in the SDTZ and the lineations oblique to the strike of the foliations in the nearby Liuling Group (Fig.3.17).

Figure 3.17 Field lineations and transposition foliations rotated to the model coordinate system. (a) Fabric data in high-strain zones. (b) Fabric data in the Liuling Group. The blue stars are the average of the lineations, and the black great circles are the average of the foliations.

Because the Liuling Group is neighboring to the SDTZ, the D_1 fabrics in the Liuling Group were influenced by the far-field tectonic oblique convergence as well as the existence of the SDTZ. The fabrics in the Liuling Group cannot be directly used to compare with the predicted fabrics in the bulk matrix, but they can be used to constrain the initial dip angle of the SDTZ. As for $\beta = 90^\circ$, fabrics inside the weak domain are independent of the convergence angle and consistently show horizontal lineations, together with the monoclinic tectonic boundary conditions, so the

symmetry of the entire system is monoclinic, and the exterior fields of the weak domain should produce monoclinic fabrics. However, the lineations in the Liuling Group are oblique on the foliation (Fig.3.17) which should result from a triclinic flow (Lin et al., 1998; Jiang and Williams, 1998). Therefore, the initial SDTZ is not vertical. If the initial dip angle of the SDTZ is relatively shallow ($\beta = 50^\circ \sim 60^\circ$), the convergence angle is constrained to $\alpha = 20^\circ \sim 30^\circ$ to produce horizontal lineations inside the SDTZ. If the initial dip angle of the SDTZ is steep ($\beta = 70^\circ \sim 80^\circ$), the convergence angle could be $\alpha = 20^\circ \sim 40^\circ$. To further extrapolate the convergence angle, the simulation of the exterior fields of the SDTZ is needed. The predicted fabrics in the exterior fields can be used to compare with the fabrics in the Liuling Group to constrain the convergence angle range.

3.4 Deformation time of the SDTZ

3.4.1 The dominant strike-slip deformation along the SDTZ and D₁ deformation in the Liuling Group

Recently, Li et al. (2017) have done some detailed work in the Shagou shear zone (the grey square in Fig.3.1b). After comparing the foliation, lineation and kinematic indicators in Li et al. (2017), we think that the deformation shown in the Shagou shear zone is same as the deformation in the Heihe area and in high-strain zones in the Danfeng area (Fig.3.13). Therefore, the deformation time of the Shagou shear zone should be the same as the deformation of the SDTZ.

In the Shagou area, LA-ICP-MS zircon U-Pb analyses of the granitic mylonites in the Shagou shear zone have been done in Li et al. (2017). The measured $^{206}\text{Pb}/^{238}\text{U}$ ages of the metamorphic zircon rims are concordant and yielded a weighted mean age

of 210.3 ± 1.5 Ma (MSWD=0.13), and zircons with clearly visible oscillatory zoning yield a mean $^{206}\text{Pb}/^{238}\text{U}$ age of 220.8 ± 1.3 Ma (MSWD=0.19) representing the age for the protolith of the granitic mylonite (Sample MD01 in Li et al., 2017). Li et al. (2017) dated a syntectonic granitic vein (SG02 in Li et al., 2017), and the crystallization age 200.7 ± 1.3 Ma represents the forming time of this syntectonic granitic vein. They (Li et al., 2017) proposed that the transpressional deformation in Shagou area was last from ca. 221 Ma to 201 Ma.

Therefore, we think that the dominant strike-slip deformation along the SDTZ and D₁ deformation in the Liuling Group occurred during 221 Ma~201 Ma (the late Triassic).

Besides the support of geochronology data in Li et al. (2017), D₁ deformation in the Liuling Group can be related to the collision between the SQB and N-SCB (late Triassic) due to their similar structural geometries. Shortening structures, such as isoclinal folds and transposition foliation, are produced by D₁ deformation in the Liuling Group. Additionally, similar structures including tight folds, foliations, and faults, have been documented in various locations in the SQB (Mattauer et al., 1985; Xu et al., 1986; Dong et al., 2011a, 2016). The sketched cross-section (Fig. 1b in Dong et al., 2016) generally illustrates shortening structures across the SQB, and the trending of the fold-thrust structures is parallel to the orogenic belt. According to previous studies, these tight fold-thrust structures were produced by the collision between the SQB and the SCB. Therefore, D₁ deformation in the Liuling Group resulted from the collision of the SQB and the N-SCB.

The Shangdan suture is a Paleozoic suture and very likely to be deformed since the Paleozoic. However, we propose that the dominant strike-slip deformation recorded in the SDTZ was mainly produced during the late Triassic. Because as an existent weak zone in the late Triassic, under a transpressional boundary condition, the SDTZ was easy to accommodate the strike-slip deformation component, and thus we can observe the dominant strike-slip deformation along the SDTZ. The shortening deformation has been preserved in the Liuling Group and the SQB.

3.4.2 D₂ deformation in the Liuling Group

D₂ deformation in the Liuling Group is characterized by the recumbent folds and the L-tectonite and can be produced by an orogen-parallel extension. An orogenic scale L-tectonite has been reported in the Tongbai orogenic belt (Liu et al., 2017). L-tectonite in the Taibaiding region of Tongbai mountain is defined by well-developed mineral lineation with weakly developed foliation. The trend of this mineral lineation is parallel to the orogenic belt with a sub-horizontally plunging angle (1° to 20°). The orientation is similar to the L-tectonite and the recumbent fold hinge lines (Fig.3.12) produced by D₂ deformation in the Liuling Group. Both fabrics can be interpreted as an orogen-parallel extension that is developed by the crustal thinning. In addition, the Tongbai-Dabie orogenic belt associated with the QOB is considered as the Central China Orogenic Belt (Fig.3.1a). The location of the L-tectonite in Tongbai can be lined up with the D₂ deformation in the Liuling Group paralleled with the extension direction of the orogenic belt where the Nanyang Basin cut across. Hence, the extensional deformation occurred in the Liuling Group was produced at the same time with the L-tectonite recorded in the Tongbai mountain. According to Liu et al. (2017),

the extensional deformation event occurred during the intra-continental orogeny from 140 to 135Ma based on geochronological data.

Therefore, D₂ deformation in the Liuling Group could be placed into the Early Cretaceous extensional event.

3.5 Summary

The deformations along the SDTZ and the Liuling Group were mainly caused by the collision of the SCB and the SQB in the late Triassic.

According to the numerical modeling results, the collision is obliquely convergent, and the convergence angle is in the range of $\alpha = 20^{\circ} \sim 40^{\circ}$.

D₂ deformation in the Liuling Group can be related to the L-tectonites in the Tongbai mountain and indicates extensional tectonism in the early Cretaceous.

Chapter 4: Deformation and Tectonic Implications of the Xinyang-Yuanlong Shear Zone in Western Qinling

4.1 Introduction

The Qinling orogenic belt (QOB) is the boundary between the North China block (NCB) and the South China block (SCB) and produced by the collision of the NCB and the SCB (Zhang et al., 2001). The Shangdan suture zone is a Paleozoic suture and marked by the discontinuously exposed Danfeng Complex that consists of ophiolitic *mélange* (Dong and Santosh, 2016). The Shangdan suture separates the QOB into the north Qinling belt (NQB) and the south Qinling belt (SQB). The QOB is divided into western Qinling and eastern Qinling (Fig.4.1) (Zhang et al., 2001). In eastern Qinling, the Shangdan tectonic zone (SDTZ) is clearly marked by the Danfeng Complex and its adjacent areas. However, as the tectonic units in western Qinling are not as clear as them in eastern Qinling and most areas are covered by the Quaternary, the questions of how the SDTZ extends to the west and what geometric features and the corresponding kinematics along the SDTZ in western Qinling are still unclear.

The Xinyang-Yuanlong shear zone is a ductile shear zone that has been recognized during a regional geological mapping project in 2004. The whole zone extends from WNW to ESE about 80 km, and the width of the shear zone can reach 2-3km. Most parts of the shear zone are not well exposed (Ding et al., 2009). However, the Xinyang-Yuanlong shear zone is considered to separate the western Qinling orogenic belt and the Qilian orogen, and it is argued to be the west extension of the

SDTZ. Before the year of 2000, previous studies generally combined the Qilian orogen and north Qinling orogen in this area and considered them as a unitary tectonic belt (Zhang et al., 1994). After the year of 2000, a lot of geochemical and petrological studies were conducted in this area, and these studies provided a basic framework of this area (Ding et al., 2004; Dong et al., 2007b; Pei et al., 2007a,b), and suggested that the Shangdan suture locates at the purple areas in Fig.4.1c. However, the kinematics of the shear zone, the deformation of the shear zone and how the deformation related to the deformation of the SDTZ in the QOB are still unclear. In addition, as the boundary of the QOB and the Qilian orogen, the Xinyang-Yuanlong shear zone locates at a key area to investigate the relationship among different tectonic units (i.e., Qilian orogen, QOB, and NCB) in central China.

We conduct detailed structural analysis and geochronological studies in this zone and try to identify the geometric features, the deformation time, and the kinematics of the zone.

Figure 4.1 Maps showing the field work area. (a) The location of the Qinling orogenic belt in China. (b) Simplified tectonic map of the Qinling orogenic belt. (c) Detailed geological map of the field work area in western Qinling (Modified from Liang et al., 2017; Pei et al.2009; Lu, 2008; Dong et al., 2007).

4.2 Field data

4.2.1 Geological setting

The Xinyang-Yuanlong shear zone is the boundary between the QOB and Qilian orogen. The geological units, involved in the shear zone, are the Qinling Complex belonging to the QOB and the Huluhe Group belonging to the Qilian orogen.

Qinling Complex

The Qinling Complex is the main part of the NQB. The Qinling Complex is predominantly made of highly deformed and metamorphosed Precambrian basements and represents the North Qinling terrane (NQT). It was proposed that the NQT was originally the southern part of the NCB and separated from the NCB during the spreading the Proterozoic Kuanping back-arc basin (Zhang and Zhang, 1995; Dong et al., 2008) or the Paleozoic Erlangping back-arc basin (Zhang et al., 1994; Zhang et al., 1995; Meng and Zhang, 1999; Zhang et al., 2001; Dong et al., 2011a,b). However, the geochemical features and metamorphic events recorded in the NQT (Zhang et al., 1996; Zhu, 2001) are different from that are recorded in the NCB (Zhao and Zhai, 2013; Zhai, 2014; Yang and Santosh, 2015) suggesting that the NQT can be regarded as a micro-continent that is independent of the NCB (Dong and Santosh, 2016). Therefore, the tectonic affinity of the NQT is still in dispute.

The metamorphic ages from the Qinling Complex are in the range of 1.2~0.9Ga (Dong and Santosh, 2016 and references therein). The Qinling Complex consists of gneisses, schists, amphibolites, marble and calc-silicate rocks (You et al., 1991). Previous studies (You et al., 1991; Zhang et al., 1994, 1995, 2001) suggested

that the sedimentary protoliths in the complex were deposited during the Paleoproterozoic. Recent studies proposed that the Qinling Complex was mainly formed during late Mesoproterozoic to early Neoproterozoic (Yang et al., 2003; Lu et al., 2009; Yang et al., 2010; Diwu et al., 2014) or during early Neoproterozoic (Shi et al., 2009; Wan et al., 2011). In addition, early Neoproterozoic granitoids (979–911 Ma) (e.g. Dehe, Zhaigen, and Niujiaoshan granitic plutons; Lu et al., 2003; Chen et al., 2004; Zhang et al., 2004; Wang et al., 2013) and Paleozoic granitoids (ca.500, 450, and 420–400 Ma; Wang et al., 2009; Wang et al., 2013; Zhang et al., 2013) have been found in this complex.

Huluhe Group

The Huluhe Group locates at the southeastern margin of the Qilian orogen and north to the Wei River. The Huluhe Group mainly contains meta-sedimentary rocks and has been further divided into two formations. The lower formation mainly distributes in the Houchuan-Zhengchuan county and the Qingshui county and includes grey to dark grey schists and meta-quartz sandstones. This unit is highly deformed and experienced a higher metamorphic grade compared with the upper formation, and the metamorphic facies can reach lower-amphibolite metamorphic facies. The primary depositional layering can barely be observed in this unit. The upper formation is in the Zhengchuan-Yangjiashi area extending east to the Qingshui county. The upper formation contains purple-grey to dark grey biotite quartz schists, phyllites, pelites, and the protolith is clastic rocks including sandstone and greywacke. The schistosity is developed, but some primary depositional layering is preserved. According to the youngest detrital zircons age group in the Huluhe Group and the crystallization age of

a granitoid dyke that was intruded into the Huluhe Group (Pei et al.,2012), the depositional time of the Huluhe Group is constrained to ca.447-434Ma and the depositional sources include the Qilian orogen, the northern margin of the western QOB, and the basement of the NCB.

4.2.2 Structural geometric features

Field work has been carried out into four areas throughout the Xinyang-Yuanlong shear zone. From east to west, they are Yuanlong, Shetang, Xinyang, and Wushan (Fig.4.1c). Outcrop-scale structures and fabrics are identified and measured in the four areas. For some complicated area (i.e., Xinyang), the detailed structural mapping is conducted.

4.2.2.1 The Yuanlong area

In the Yuanlong area, the shear zone is developed in granitic and felsic gneisses. In addition, there are some mafic dykes and granitoid pegmatitic dykes intruded in the deformed rocks and parallel to the foliations, but there is no deformation-related fabric inside the dykes (Figs.4.2a,b). Fig4.2c shows the lower-hemisphere equal-area projection of transposition foliations and mineral lineations throughout this area. The overall average foliation is steeply dipping and strikes WNW-ESE, and the corresponding lineations trend to SE plunging $9^{\circ}\sim 50^{\circ}$ (white-filled dots, Fig.4.2c,d). Well-developed shear-sense indicators can be observed on the sections that are subparallel to the lineations and perpendicular to the foliations (Figs.4.2f-j) showing a dextral sense of shear.

Figure 4.2 Photos and fabric data from the Yuanlong area. Pictures to show granitic pegmatitic dyke and mafic dyke (a,b), mineral lineations (d) and shear-sense indicators (e-i) in the Yuanlong are; (c) is the equal-area lower-hemisphere projection of the transposition foliations and mineral lineations in the Yuanlong area: triangles are the poles to the foliations and dots represent the lineations. Shear-sense indicators are all observed on sub-horizontal surfaces, and the sub-vertical sections do not show good shear-sense indicators.

4.2.2.2 The Shetang area

In the Shetang area, the shear zone is developed in granitic gneiss, meta-pelites, and calc-silicates from the Qinling Complex (Fig.4.3a). There are some mafic dykes that intruded into the calc-silicates, and the mafic dykes are parallel to the transposition foliations in the calc-silicates (Fig.4.3d). To the north of the highly deformed rocks, there is a granitoid pluton and no deformation-related fabric in the granitoids (Fig.4.3a). To the north of the pluton, the Huluhe Group is well exposed (Figs.4.3e-g). The foliation in this area is defined by schistosity, and the highly deformed quartz veins can be observed along the layers (Figs.4.3f,g). Fig.4.3c and Fig.4.3b are the equal-area projections of transposition foliations and stretching lineations from the Qinling Complex, and schistosity and mineral lineations from the Huluhe Group, respectively.

The foliation and lineation data in Fig.4.3c are divided into two groups: In the 1st group, the foliations (blue great circles) are shallowly dipping to the SE and SW (dip angles $\sim 20^{\circ}$ - 30°), and the corresponding lineations (blue-filled dots) are oblique to the strike of the foliations (pitch $\sim 10^{\circ}$ - 70°); In the 2nd group, the foliations steeply strike WNW-ESE with lineations (green circles) along the strike or oblique to the strike. The dashed-line area in the Qinling Complex in Fig.4.3a contains meta-pelites and calc-silicate with the fabrics in the 2nd group. The rest of the Qinling Complex in the Shetang area is mainly composed of granitic gneiss. Schistosity in the Huluhe group (Fig.4.3b) is shallowly dipping to NE with lineations oblique on foliations.

Figure 4.3 Geological map, photos and fabric data from the Shetang area. (a) A detailed map of the Shetang area. (b) and (c) are lower-hemisphere equal-area projections of the schistosity & mineral lineations in the Huluhe Group and transposition foliations & stretching lineations in the Qinling Complex, respectively. Triangles are the poles to the foliations and dots represent the lineations. (d) The picture to show the mafic dykes southern part of the Shetang area. The country rocks are highly deformed calc-silicates, and the dykes are parallel to the transposition foliations. The scale of the picture is a stone wall at the bottom of the picture, and its height is ~1.5m. (e-g) are the deformed Huluhe Group in the northern edge of (a). The scale of (e) is the height (~0.5m) of the white stakes on the road.

Figure 4.4 Geological map, photos and fabric data from the Xinyang area. (a) A geological map to show the Moshi valley and Xiweizi valley in the Xinyang area. (b,c) Shear-sense indicators on sub-horizontal surfaces in the Xiweizi valley to show a dextral sense of shear. (d,e) The equal-area lower-hemisphere projections of the transposition foliations and mineral lineations in the Moshi valley and Xiweizi valley, respectively: triangles are the poles to the foliations and dots represent the lineations.

4.2.2.3 The Xinyang area

In the Xinyang area, the deformed rocks are separated by the Wei River (Fig.4.4a). To the south of the river (the Xiweizi Valley), the deformed rocks are granitic gneiss where rotated clasts and trails are observed on sub-horizontal planes indicating a dextral sense of shear (Figs.4.4b,c). The transposition foliation steeply strikes E-W and mineral lineations gently plunge to WSW (Fig.4.4e).

To the north of the river, deformed rocks are more heterogeneous, consisting of meta-pelite, calc-silicate, marble, metamorphosed diabase and meta-basalt. Meta-sedimentary units are mostly deformed with well-developed transposition foliations and stretching lineations. Generally, the diabase has no recognizable fabrics, and the meta-basalt has a weak lineation and foliation. The equal-area lower-hemisphere projections of foliations and lineations in the Moshi Valley are shown in Fig.4.4d. The foliations strike WNW-ESE steeply dipping, and lineations form a broad girdle along the average transposition foliation. As we think that the variation of the lineation is due to the heterogeneity of the deformed rocks, a detailed structural mapping in this area is carried out, and we try to divide rocks into different units and map the fabrics in each unit (Figs.4.5-4.8).

The whole Moshi Valley is divided into 22 units according to the lithology and structural variations (Fig.4.5a). The metamorphosed diabase and meta-basalt units are labeled by green numbers (e.g., units 2, 4, 6), and the black numbers represent meta-sedimentary rock units (e.g., units 1, 3, 5). There are three units that contain various

structures and lithologies, and a more detailed mapping of each unit is conducted (i.e., units 12, 14, 20).

The metamorphosed diabase units generally show no deformation-related fabrics inside the units (Fig.4.5b). For example, Fig.4.5b shows the boundary between unit 4 and unit 5. The left side in Fig.4.5b is unit 4, and it is a metamorphized diabase. Except for some fractures, there is no fabric inside the diabase (i.e., transposition foliations or mineral lineations), but the whole unit strikes NW-SE. The right side in Fig.4.5b is unit 5, and it contains calc-silicates and meta-pelites. The foliations and lineations are well-developed inside unit 5. The meta-sedimentary units are generally highly transposed (Figs.4.5b,c). The shear-sense indicators can be observed on sub-horizontal sections and consistently show a dextral sense of shear (Figs.4.5e-h). As in units 12, 14 and 20, the mafic dykes are too small to be mapped on Fig.4.5a, and the structures are more complicated than structures in other units, we conduct more detailed mappings in these three units.

Fig.4.6a is the detailed mapping of unit 12. Fig.4.6c shows that a deformed meta-basalt (sub-unit 12-4) was boudinaged and the country rocks are calc-silicates. Some isoclinal folds can be observed in unit 12 (Fig.4.6d), and they are intra-folia and should be developed during the formation of the transposition foliation. Fig.4.6b (12-14) represents a projection of the isoclinal fold axial plane and hinge line (orange dot and great circle), and the orientation is similar to the transposition foliation and mineral lineations in the unit. Sub-unit 12-15 is a mafic rock unit. It contains undeformed mafic

rocks and highly transposed rocks (Fig.4.6e). The highly transposed rocks contain massive quartz veins, and the quartz veins are transposed (right side of Fig.4.6e).

Figure 4.5 Detailed mapping and photos from the Moshi valley. (a) Detailed mapping of the Moshi valley. (b) A photo to show the boundary between unit 4 (left side) and unit 5 (right side): unit 5 is highly deformed, but unit 4 has no internal fabrics. (c) A photo to show the highly transposed calc-silicates in unit 1

(sub-horizontal surface). (d) Transposition foliations and mineral lineations of each unit (note that the mafic rock units generally do not show fabrics except for units 13, 15, 22). (e-f) Photos to show shear-sense indicators on sub-horizontal surfaces. They consistently show a dextral sense of shear.

Fig.4.7a is the detailed mapping of unit 14. Intra-folia folds are widespread in unit 14. There are two generations of intra-folia folds (F_{1a} and F_{1b}). In some outcrops, we can observe the overprinting relationships (Figs.4.7c-f) between F_{1a} and F_{1b} , and thus we can distinguish between F_{1a} and F_{1b} . In most cases, we cannot distinguish between them (Fig.4.7g), so the intra-folia folds are labeled as $F_{1a/b}$.

Fig.4.8a is the detailed mapping of unit 20. In this unit, F_1 folds are widely distributed (Figs.4.8c-i). In addition, F_2 folds can be observed (Figs.4.8i-l). The transposition foliations that were developed during $F_{1a/b}$ are folded. However, F_2 folds are only observed in this unit, and the orientations of their fold axial planes are close to the transposition foliation (S_t) and the axial planes of F_1 . Additionally, asymmetric F_2 folds consistently show a dextral sense of shear. Thus, we think that F_2 folds were developed during the later deformation process but not another deformation event.

Well exposed Huluhe Group is northeast of the Xinyang mapping area (Fig.4.1c). Schistosity is well-developed in meta-pelite and meta-sandstone. There is no lineation on schistosity, but the abundant rootless folds of quartz veins are in the deformed rocks (Figs.4.9a-d) indicating that this rock unit is highly deformed. The hinge line of the intra-folia folds and the schistosity are plotted on lower-hemisphere equal-area projection (Fig.4.9e).

Unit12

Figure 4.6 Detailed mapping and photos from unit 12. (a) A more detailed mapping of unit 12. (b) Transposition foliations (red triangles and black great circles) and mineral lineations (green dots) of each sub-unit (note that sub-unit 12-14 contains a plot of fold hinge line (orange dot) and axial plane (orange triangle and great circle)). (c) A photo (sub-unit 12-4) to show the boudinaged meta-basalt. The boudins are meta-basalts, and country rocks are calc-silicates. Both meta-basalts and calc-silicates show well-developed foliations. (d) A photo to show the parasitic folds in sub-unit 12-14. (e) A photo (sub-unit 12-15) to show undeformed diabase and highly transposed mafic rocks (note that there are voluminous quartz veins in the deformed rocks).

Unit14

Figure 4.7 Detailed mapping and photos from unit 14. (a) A more detailed mapping of unit 14. (b) Transposition foliations (red triangles and black great circles) and mineral lineations (green dots) of each sub-unit. (c-g) Photos to show two generations of folds (F_{1a} and F_{1b}) in unit 14.

Figure 4.8 Detailed mapping and photos from unit 20. (a) A more detailed mapping of unit 20. (b) Transposition foliations (red triangles and black great circles) and mineral lineations (green dots) of each sub-unit. Fold hinge lines (orange dots) and axial planes (orange triangle and great circles) of $F_{1a/b}$ in each sub-unit. Fold hinge lines (purple dots) and axial planes (purple triangles and great circles) of F_2 in each sub-unit. (c-l) Photos to show $F_{1a/b}$ and F_2 .

(e) Lower-hemisphere equal-area projection of the schistosity (red triangles and black great circles) and the hinge lines of the intra-folia folds defined by quartz veins (purple dots).

4.2.2.4 The Wushan area

In the Wushan area, well-developed lineations and foliations are found in a deformed diabase outcrop and metapelites, and dextral shear-sense indicators are observed on horizontal planes (Figs.4.10a,b). The equal-area lower-hemisphere projections of lineations and foliations are shown in Fig.4.10c. Most of the stretching lineations are along the strike of the foliations. The foliations are steeply dipping and striking NW-SE.

Figure 4.10 Photos and fabric data from the Wushan area. (a,b) Photos on sub-horizontal surfaces to show a dextral sense of shear in Wushan. (c) Lower-hemisphere equal-area projection of transposition foliations and mineral lineations in Wushan.

4.3 Geochronology data

There are several dykes in the shear zone. Zircon dating of these dykes is used to constrain the deformation time.

4.3.1 Sample descriptions

4.3.1.1 Samples from the Yuanlong area

In the Yuanlong area, there are several granitoid pegmatite dykes. These dykes are intruded in the granitic and felsic mylonites. Although these dykes are undeformed, the dykes are all subparallel to the foliations, and in addition, there are flanking structures around the dykes (Fig.4.11). Therefore, we suspect that these dykes intruded into the mylonites before the deformation, and the crystallization age of these dykes can be used to limit the time before the deformation.

These samples are TS1406, TS1408-1, TS1408-2.

4.3.1.2 Samples from the Shetang area

In the Shetang area, several granitoid pegmatitic dykes have been found in the deformed Qinling Complex. These dykes were intruded in the deformed rocks (Fig.4.12). There are two circumstances regarding the relation between the dykes and the deformation: 1) the dykes could be boundinaged during the deformation, and the inner boundin parts were not deformed; 2) the dykes could intrude into the deformed rocks after the deformation. It is hard to distinguish between these two circumstances.

These dykes are ST1502, ST1510-1, ST1510-2, ST1511, ST1515.

Figure 4.11 Field photos of granitic pegmatitic dykes from the Yuanlong area. (a) TS1406, (b) TS1408-1, (c)TS1408-2. Note the flanking structures beside the pegmatitic dyke.

Figure 4.12 Field photos of granitic pegmatitic dykes from the Shetang area. (a) ST1502, (b) ST1511, (c) ST1515, (d) ST1510-1, (e) ST1510-2. Their locations are on Fig.4.3a. The black wire in (b) is served as a scale and about 5 meters in length.

To the north of the deformation zone, there is an undeformed granitoid body. Two samples are collected from this granitoid body, and they are ST1512, ST1513 (Fig.4.3a).

4.3.1.3 Samples from the Xinyang area

In the Xinyang area, there is a syn-deformation dyke: the body of the dyke cut the foliation, and the two tails of the dyke were deformed along the foliation (Fig.4.13c). Thus, the crystallization age of this dyke can constrain the deformation time. This dyke is XY1605. This dyke is a syenite dyke and highly weathered.

There are other highly deformed dykes in this region (Figs.4.13a,b). They are XY1601A, XY1601B, XY1602. XY1601A and XY 1602 are two meta-mafic dykes, and XY1602B is a granitoid dyke.

4.3.2 Analytical procedures

Zircon separation and morphology: Zircons are selected by crushing, initial heavy liquid separation techniques and subsequent magnetic separation handpicked and mounted. The mounts are ground and polished to half of the zircons' thickness. Zircons are photographed in transmitted and reflected light for further analysis. Cathodoluminescence (CL) imaging of zircons is conducted to reveal their internal structures. The CL imaging is performed by using a Quanta 400FEG environmental scanning electron microscope equipped with an Oxford energy dispersive spectroscopy system and a Gatan CL3+ detector. This process is completed at Xi'an Lucky-stone Geological Service, China.

Figure 4.13 Field photos to show dykes from the Xinyang area. (a,b) XY1601A, XY1601B, XY1602, (c) XY1605 (syenite, the body cuts the transposition foliation, and the tail is deformed along the transposition foliation).

LA-ICP-MS U-Pb dating: U-Pb zircon analyses are performed on a laser-ablation system with an Agilent 7500a ICP-MS instrument equipped with a 193 nm ArF excimer laser at Northwest University, China. The laser beam of 35 μm in diameter and repetition rate of 7 Hz is adopted throughout the whole study. Nist610 glass is used as the trace elements external standard. Standard zircon 91500 is used as an external standard for isotope fractionation. Every five analyses are followed by one analysis of standard zircon 91500, and every 10 analyses are followed by measurements of GJ-1 and Nist 610.

Data processing: $^{207}\text{Pb}/^{206}\text{Pb}$, $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$, and $^{208}\text{Pb}/^{232}\text{Th}$ ratios are calculated using GLITTER 4.0 (Macquarie University, Sydney, Australia). Concordia diagrams and weighted mean U-Pb ages are processed by using ISOPLOT 3 (Ludwig, 2003). Ages and Concordia plots are reported at the 2σ error, while the uncertainties for weighted mean ages are at 95% confidence level.

4.3.3 Geochronological results

According to external morphology, internal zoning, Th/U ratio and REE pattern, the analyzed zircons can be classified into magmatic and metamorphic groups. However, some people argue that a more thorough interpretation is relating the differences and changes to growth or recrystallization mechanisms: only zircon grown by solid state (metamorphic) reactions may be called metamorphic, whereas zircon crystallized from melt is magmatic, and zircon crystallized from fluids is hydrothermal. Besides the difference in growth mechanism, an existing zircon could be altered by other processes (i.e., metamictisation, annealing, recrystallization, dissolution-reprecipitation) and thus the above criteria could be affected by these processes. For

example, Th/U ratios of metamorphic zircons are not necessarily less than 0.1, and igneous zircons do not necessarily develop oscillatory zoning (Corfu et al., 2003). Undoubtedly, there is no one standard rule to distinguish among different types of zircons, and the above criteria are used together to make the most reasonable interpretation. In the following classifications, the U-Pb results are grouped into magmatic ages and metamorphic ages. The magmatic ages group generally displays well-developed zoning, and Th/U ratios of them are greater than 0.1 and show a typical REE pattern of unaltered igneous rocks. The other ages are all grouped into metamorphic ages, so the metamorphic age group is not a strict metamorphic age, and it may include ages that reflect other alteration processes or mixed processes.

The $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$, and the $^{207}\text{Pb}/^{206}\text{Pb}$ ages can be calculated from lead and uranium isotopes. In addition, the $^{208}\text{Pb}/^{232}\text{Th}$ age can be calculated through the thorium series decay but rarely used in zircon geochronology. ^{235}U is not directly measured from the mass spectrometer and is calculated from the fixed $^{238}\text{U}/^{235}\text{U}$ ratio (Hiess et al., 2012), and the $^{207}\text{Pb}/^{235}\text{U}$ is mainly used to calculate the discordance of analysis (e.g., Spencer et al., 2016). Therefore, two isotopic ages (i.e., $^{206}\text{Pb}/^{238}\text{U}$ and the $^{207}\text{Pb}/^{206}\text{Pb}$) are used for further analyses (e.g., weighted mean average calculation, age spectra plot). It is generally accepted that the $^{207}\text{Pb}/^{206}\text{Pb}$ age is used for zircons older ages and the $^{206}\text{Pb}/^{238}\text{U}$ age is used for younger ones. However, ~1.0 Ga, ~1.2 Ga or ~1.5 Ga cutoffs are proposed in the literature (e.g., Gehrels et al., 2008; Voice et al., 2011; Roberts and Spencer, 2014). According to the clusters of the dating results, for the following analyses, ~1.5Ga is used as the cutoff in this study.

Zircon Rare-earth element (REE) abundances for the samples are normalized to chondrite values (Sun and McDonough, 1989) and plotted on logarithm coordinates to establish the REE patterns. The REE is grouped into light REE (LREE, La-Pr), middle REE (MREE, Nd-Gd) and heavy REE (HREE, Tb-Lu). According to Hoskin and Schaltegger (2003), the REE pattern for unaltered igneous zircon is characterized by a steeply-rising slope from the LREE to the HREE with a positive Ce-anomaly and negative Eu-anomaly, and metamorphic zircons can show patterns similar to the igneous zircon pattern or different from it.

The quality of the analytical data from the Yuanlong, Shetang and Xinyang areas is low. Namely, a large amount of analyzed spots show discordant ages and most of the zircons are xenocrystic zircons. Therefore, the detailed descriptions and results of each sample are in Appendix E. Only the results of XY1605 (Fig.4.13c) is discussed here, as it contains the youngest zircon age, and the dyke shows a clear relationship with the deformation in the Xingyang-Yuanlong shear zone.

56 spots are analyzed from XY1605 (Fig.E12), and 35 analyses of the 56 spots show concordant ages ($\text{disc.\%} \leq \pm 5\%$). According to the structures of zircons in CL images, Th/U ratios and the REE patterns, magmatic ages from the 35 zircons are identified. The concordant magmatic ages can be divided into the following groups: 1769.8 \pm 39.99Ma (1 analysis, Spot No.24); 1501.9Ma (1 analysis, Spot No.05); 1089.8~1002 (3 analyses, Spot No.01, 07, 14); 999.5~882.6Ma (3 analyses, Spot No.04, 29, 49); 844.9~604.1 (3 analyses, Spot No.16, 25, 26); 490.3 \pm 7.03Ma (1 analysis, Spot No.47); 467.1~462.8 (2 analyses, Spot No.55, 56); 451~447.6Ma (analyses, Spot No.13, 21, 22); 441.6 \pm 4.02Ma (1 analysis, Spot No.23);

423.3±4.89Ma (1 analysis, Spot No.33); 408.1~405.5 (2 analyses, Spot No.31, 37); 374.6±4.7Ma (1 analysis, Spot No.03); 357.9±4.53Ma (1 analysis, Spot No.37); 234.5±2.98Ma (1 analysis, Spot No.15); 212.5±2.12Ma (1 analysis, Spot No.11); 201.8±2Ma (1 analysis, Spot No.10).

As the youngest magmatic events in this area is the early Mesozoic event (Fig.4.16), the youngest age (i.e., 201.8±2Ma) in XY1605 is likely to indicate the crystallization age of this dyke instead of inherited from country rocks.

4.4 Interpretations and summary

4.4.1 Xenocrystic ages from the samples

The ages from the geochronological dating results expand in a long range, as most of the ages are xenocrystic ages. Although they may not be able to indicate the deformation time of the Xinyang-Yuanlong shear zone, they contain information about the tectonic evolution of this area. Therefore, we compare the age spectra from our samples with the previous geochronology studies throughout this area and try to find out the tectonic evolution information in the geochronology data. The above “metamorphic” age group is not critically the metamorphic ages, as to study the metamorphic zircons and relate the metamorphic ages to the metamorphism and further the tectonism, more petrology and geochemical studies are needed, which is not the key problem that we try to solve in this work. Therefore, we mainly compare the whole ages and magmatic ages with previous studies.

In principle, dykes can capture xenocrystic zircons from anywhere they have passed by. However, as the samples are all in the Xinyang-Yuanlong shear zone that

is composed of the Qinling Complex and the Huluhe Group, the geochronology studies in these two units are reviewed and compared with the above results.

4.4.1.1 The Archean and Proterozoic age group (2623.6~646.3Ma, 213/377 analyses)

Figure 4.14 Age spectra from this study and previous studies. (a) Archean and Proterozoic age spectrum from this work. (b) Detrital zircon ages from the Huluhe Group (Pei et al., 2012). (c) Detrital zircon ages from the sedimentary units in the Qinling Complex (Wu and Zheng, 2013).

The age spectrum of Precambrian ages is in Fig.4.14a. The spectrum is comparable with the detrital zircon ages from the Huluhe Group (Fig.4.14b; Pei et al., 2012) and sedimentary rocks of the Qinling Complex (Fig.4.14c; Wu and Zheng, 2013 and reference therein). The age populations in Fig.4.14a are all subsets of the age spectra from the detrital zircons of the Huluhe Group and the Qinling complex

The xenocrystic ages show age peaks at ca.0.90-1.0Ga. Neoproterozoic granitoids showing emplacement ages from ca.890 to 980Ma have been reported in the Qinling Complex (e.g., Pei et al., 2003; Wang et al., 2003; Chen et al., 2006; Shi et al. 2009) and in the Qilian orogen (e.g., Guo and Zhao, 1999; Wan et al., 2003; Yong et al., 2008). Similar metamorphic ages (ca.859~978Ma) from the Qinling Complex by the Rb-Sr, Ar/Ar and Sm-Nd methods (e.g., Zhang et al., 1994; Wang et al., 2003; Dong et al., 2011c) have been obtained. All these ages are related to the Grenvillian orogeny (Dong et al., 2011a) and may be a response to the assembly of the supercontinent Rodinia in the early Neoproterozoic. According to Dong and Santosh (2016), the Neoproterozoic granitoids in the Qinling Complex indicate the southward subduction of the Kuanping Ocean and later collisional and post-collisional tectonic settings between the NCB and the NQB. The ages that are younger than 800Ma indicate an extensional setting after the collision between the NCB and NQB (Wang et al., 2013).

During 1.45~1.1Ga, the Qinling terrain was separated from the NCB by the Kuanping Ocean (Dong and Santosh, 2016), so the xenocrystic ages that are older than 1.1Ga represent the basement rocks (2.5~2.8Ga), Mesoproterozoic volcanic rocks and

Paleoproterozoic and Mesoproterozoic sedimentary rocks of NCB (Wu and Zheng, 2013).

4.4.1.2 The Paleozoic age group (524.3~343.6Ma, 159/377 analyses)

Figs.4.15a,b show the U-Pb results in the Paleozoic including the total results (Fig.4.15a) and the magmatic ages (Fig.4.15b). The ages that are younger than 445Ma do not overlap the detrital age spectra compared with the detrital ages in Figs.4.14b,c, and thus the magmatic zircons with age younger than 445Ma indicate the crystallization age of the dykes.

Fig.4.15c shows the early Paleozoic granitoids in the north Qinling belt from Zhang et al. (2013). Previous studies suggest that the early Paleozoic granitoids are arc magmatism and associated with the northward subduction of the Shangdan Ocean (e.g., Zhang et al., 2001; Ratschbacher et al., 2003; Dong et al., 2001b), while, recently, Zhang et al. (2013) grouped the early Paleozoic granites ages into three stages according to the age population. Based on the minerals in the plutons and geochemical features, Zhang et al. (2013) suggested that the first-stage (ca.500Ma) plutons are mainly from partial melting of crustal rocks during the crustal collision between the SQB and S-NCB; the second-stage (ca.450Ma) granitoids were generated from a mixed source of mantle and crust materials indicating a post-collisional setting; the third-stage (ca.420-400Ma) granitoids were formed from high differentiation of crust-derived magma in an extensional setting. The above interpretations of the early Paleozoic granitoids can be correlated to the HP-UHP metamorphism at ca.500Ma and

two stages of retrograde metamorphisms at ca.470-450Ma and ca.420-400Ma (Liu et al., 2016).

Figure 4.15 Paleozoic age spectra from this study and Paleozoic granitoids in the north Qinling belt. (a) the Paleozoic age spectrum from this work, (b) the magmatic Paleozoic age spectrum from this work, (c) Early Paleozoic granitoids in the north Qinling belt (from Zhang et al., 2013).

4.4.1.3 The Mesozoic age group (234.5~121.7Ma, 5/377 analyses)

There are only 5 U-Pb ages in this group: 3 magmatic ages (234.5-201.8Ma) and 2 ‘metamorphic’ ages (228.8 and 121.7Ma). Early Mesozoic magmatism between 252 and 185Ma is widespread in Western Qinling (Fig.4.16; Wang et al., 2013). The tectonic setting of the early Mesozoic magmatism is still in dispute. Zhang et al. (2001) proposed that Triassic granitoid magmatism resulted from northward subduction of Paleo-Tethyan oceanic crust, and some people argued that Triassic granitoids were developed during post-collisional delamination of thickened orogenic crust (e.g., Wang et al., 2005, 2007, 2011; Zhang et al., 2005; Qin et al., 2009, 2010). Wang et al. (2013) and Dong and Santosh (2016) suggested that early stage (250-240Ma) granitoids were related to northward subduction of the Mianlue Ocean to the SQB, and late stage (225-185Ma) granitoids indicate syn- or post-collision between the SQB and the SCB.

Figure 4.16 Distribution of granitoids with emphasis on Mesozoic granitoids in the Qinling orogenic belt (Fig.9 in Wang et al., 2013).

4.4.2 Deformation time and kinematic interpretations of the Xinyang-Yuanlong shear zone

According to the observations and geochronological studies in this study, and previous studies in this region, the Xinyang-Yuanlong shear zone may have experienced two deformation events. The work areas are summarized and interpreted as follows.

4.4.2.1 Deformation time in the Yuanlong area

Ding et al. (2009) have obtained a biotite $^{40}\text{Ar}/^{39}\text{Ar}$ age from the felsic gneiss in the Yuanlong area ($351.70 \pm 1.72\text{Ma}$). As the deformation fabrics in the Yuanlong area are clearly ductile deformation (Figs.4.2) and must have been formed under the temperature that is higher than $\sim 300^\circ\text{C}$ (the closure temperature of biotite), the ductile fabrics in the mylonites where the biotite $^{40}\text{Ar}/^{39}\text{Ar}$ age obtained in the Yuanlong area was mainly formed during a deformation event that is order than ca.352Ma. The ‘metamorphic’ age ($384.7 \pm 3.3\text{Ma}$, Spot No.16) in TS1408-2 may reflect that the zircon was reworked during the deformation.

4.4.2.2 Deformation time in the Xinyang area

Deformation in Xinyang can be divided into three districts according to the work locations: District 1, the Xiweizi valley (Figs.4.1c,4.4a); District 2, the Moshi valley (Figs.4.1c,4.4a); District 3, northeast of the Xiweizi and Moshi valleys (Figs.4.1c,4.9).

(1) District 1, the Xiweizi valley

The deformed rocks in the Xiweizi valley are granitic mylonites (Figs.4.4b,c), and Ding et al. (2009) have obtained a biotite $^{40}\text{Ar}/^{39}\text{Ar}$ age from the deformed rocks in the Xiweizi valley ($347.95\pm 2.17\text{Ma}$). The age indicates that the fabrics in the Xiweizi valley should be formed in a deformation event before ca.348Ma. Compare with the deformation time in Yuanlong, the ductile fabrics in the Xiweizi valley was probably formed in the deformation event between ca.385Ma and 352Ma.

(2) District 2, the Moshi valley

In the Moshi valley, the syn-deformation syenite dyke (XY1605, Fig.4.13c) indicates the deformation time. The crystallization age of this dyke is $201.8\pm 2\text{Ma}$, and thus the dominant deformation in this valley should occur around 202Ma. However, the Xiweizi valley is south to the Moshi valley and should contain older deformation fabrics (ca.385-352Ma). It is highly likely that the deformed rocks in the Moshi valley (or in the whole area) had experienced at least two deformation events (ca.385-352Ma, ca.202Ma). Therefore, there are three types of fabrics in the Moshi valley: one type is the newly developed fabrics from the ca.202Ma deformation event; the second type contains the fabrics that were originally developed from the ca.385-352Ma

deformation event but reworked during the ca.202Ma deformation event; the last type includes the fabrics that were developed from the ca.385-352Ma deformation but not reworked during the ca.202Ma deformation. In addition, the detailed mappings (Figs.4.5-4.8) in the Moshi valley show that each domain contains comparatively uniform fabrics, which suggests that the heterogeneous composition of the deformed rocks plays a key role to produce heterogeneous fabrics (Fig.4.4d) in the Moshi valley.

(3) District 3, northeast of the Xiweizi and Moshi valleys

Unlike the fabrics in Districts 1&2, the Huluhe Group in District 3 were deformed into S-tectonites and does not develop mineral lineations. Furthermore, the fold axes of the intra-folia folds spread out along the average transposition foliation (Fig.4.9e). Therefore, fabrics in this area reflect a shortening deformation. This deformation probably occurred during the collision between the NQB and the Qilian orogen.

4.4.2.3 Deformation in the Shetang area

The steeply dipping transposition foliations in the Shetang area are constrained in the dashed-line region in Fig.4.3a, but the geochronological samples of granitic pegmatites are all from southern part of the Shetang area (Fig.4.3a). In the Qinling Complex, some foliations are extremely shallow (blue great circles in Fig.4.3f) with oblique lineations. These fabrics may be developed during Precambrian and correlated with the formation of the metamorphic basement rocks. Some foliations are moderately steep and strike WNW to ESE with oblique lineations, and this set of fabrics is related to the ca.390-352Ma deformation. The steeply dipping foliations that

are striking NW to SE (grey great circles in Fig.4.3f and dashed-line region in Fig.4.3a) are correlated to the ca.202Ma deformation. The deformation in the Huluhe group corresponds to the collision between the NQB and the Qilian orogen like the District 3 in the Xinyang area.

Li (2008) obtained a biotite $^{40}\text{Ar}/^{39}\text{Ar}$ age ($355.2\pm 2.6\text{Ma}$) from the deformed Huluhe Group in the Qingshui county that is northeast of our Shetang work area. This age indicates that the deformation of the Huluhe Group in District 3 in the Xinyang area and the deformation of the Huluhe Group in the Shetang area occurred before ca.355Ma. Combining with the age in Yuanlong, this deformation occurred between ca.385-355Ma corresponding with the collision among the NQB, the NCB and the Qilian orogen.

4.4.2.4 Deformation in the Wushan area

Li (2008) has obtained a muscovite $^{40}\text{Ar}/^{39}\text{Ar}$ age ($226.76\pm 2.21\text{Ma}$) from the granitic mylonites in Wushan. The deformed rocks in the Wushan area are greenschists, granitic mylonites and felsic mylonites. The muscovite $^{40}\text{Ar}/^{39}\text{Ar}$ age ($226.76\pm 2.21\text{Ma}$) from granitic mylonites may indicate that the deformation in this area occurred around 227Ma. This deformation may be correlated with the ca.202Ma deformation in the Moshi valley. The youngest strike-slip dominant dextral shear deformation occurred between ca.227Ma and 202Ma.

One exception is a recent work in the Wushan area (Liang et al., 2017). They dated an undeformed granitic intrusion in granitic mylonites, and the U/Pb zircon age of this intrusion is 403Ma. Combined with previous tectonic evolution models of

Qinling orogenic belt, they concluded that the Wushan ductile shearing occurred between ca.420 and 403Ma. From the picture of the undeformed intrusion (Fig.3d in Liang et al., 2017), the intrusion could act as a rigid body or be a product of boudinage during the deformation.

4.4.2.5 The kinematics of the Xinyang-Yuanlong shear zone

Overall, the dominant fabrics that are currently observed throughout the Xinyang-Yuanlong shear zone were produced by the deformation between ca.227Ma and 202Ma. The heterogeneity of the fabric data throughout the Xinyang-Yuanlong shear zone mainly resulted from the heterogeneity of the deformed rocks and can be explained by the multi-order power-law approach (MOPLA) that has been introduced in Chapter 1.

Fig.4.17c shows the overall fabrics across the Xinyang-Yuanlong shear zone. The fabrics in the Yuanlong, Shetang, Xiweizi, Wushan areas are relatively uniform, but the overall lineations spread out on the average foliation with the concentration close to the strike of the foliation. As the deformed rocks are extremely heterogeneous in the Moshi Valley, the overall lineations in the Moshi Valley spread along the average foliation, and the fabric in each mapping unit is relatively uniform (Figs.4.4-4.8). According to MOPLA, the Xinyang-Yuanlong shear zone can be considered as a Representative Volume Element (RVE) in MOPLA, and the RVE is made up by many Rheologically Distinct Phases (RDPs) (Fig.4.17a). The deformed rock units in the Yuanlong, Shetang, Xiweizi Valley, Moshi Valley and Wushan areas can be regarded as different RDPs. Except for the fabrics in the Moshi Valley, the fabrics in

each RDP show a roughly uniform distribution. The deformed rocks in the Moshi Valley can be regarded as an RDP that consists of many 2nd-order RDPs (Fig.4.17b), and in each 2nd-order RDP, the fabrics are relatively uniform.

Jiang (2014) has systematically simulated the fabric patterns that are produced by the different boundary conditions based on MOPLA. The velocity gradient tensor in Jiang (2014) is written in the following format

$$\mathbf{L} = \begin{pmatrix} 0 & \cos \alpha & 0 \\ 0 & -\sin \alpha \sin \beta & 0 \\ 0 & -\sin \alpha \cos \beta & \sin \alpha \sin \beta \end{pmatrix}, \text{ where } \alpha \text{ is the convergence angle and } \beta \text{ is}$$

the dip of the deformation zone and set to 70° in Jiang (2014) (Fig.4.18). Here, the simulation results (Fig.4.19) in Jiang (2014) are compared with the measured data in this work.

The overall stretching lineations throughout the Xinyan-Yuanlong shear zone are mostly like the first and second rows of the simulation results (i.e., $\alpha = 0^\circ, 5^\circ$) indicating a strike-slip shear dominant deformation. This interpretation is consistent with the fact that all the shear-sense indicators are observed on the horizontal or sub-horizontal sections.

Figure 4.17 A conceptual diagram to show the interpretation of the fabric data from the Xinyang-Yuanlong shear zone. (a) A conceptual diagram showing that the Xinyang-Yuanlong shear zone can be regarded as a Representative Volume Element (RVE) that is composed of many Rheologically Distinct Phases (RDPs). One can refer to Chapter 1 for the detailed concepts of RVE and RDPs. (b) One RDP can consist of a 2nd-order RDPs, which is the case of the deformed rocks in the Moshi Valley. (c) The equal-area lower-hemisphere projection of the overall transposition foliations and stretching lineations throughout the Xinyang-Yuanlong shear zone with respect to the model coordinate system in Fig.4.18. The black great circle is the average of the transposition foliations.

Figure 4.18 Transpression model in Jiang (2014). (a) Inclined transpression model in Jiang (2014). s.s.shr.: strike-slip shear; d.s.shr.: dip-slip shear. (b) The coordinate system that is used to make the equal-area projection in Fig.4.34 (Fig.6 in Jiang, 2014).

Figure 4.19 Model predicted ‘stretching lineations’ patterns produced by different boundary conditions in Jiang (2014). The ‘stretching lineations’ are defined by the maximum principal finite strain axes in RDPs throughout the deformation zone (Fig.10 in Jiang, 2014).

4.5 The deformation along the SDTZ in western Qinling

There are at least two deformation events in the Xinyang-Yuanlong shear zone in western Qinling. D₁ deformation occurred between ca.385Ma and 355Ma. D₁ deformation has been preserved in the Huluhe Group that is north of the Xinyang-Yuanlong shear zone and shows a NE-SW shortening deformation. D₂ deformation occurred between ca.227-202Ma and produced the dominant fabrics that are currently observed in the Xinyang-Yuanlong shear zone. D₂ deformation is a strike-slip dominant deformation with a dextral sense of shear.

The Shangdan suture was defined by the Danfeng Complex (purple areas in Fig.4.1c). In western Qinling, the mafic and ultramafic rocks in the Wushan and Guanzizhen areas are interpreted to be part of the Danfeng Complex (Fig.4.1). Lu (2008) has conducted extensive field work in the Wushan, Guanzizhen and Tangzang areas and, similarly, observed the dextral shear strike-slip dominant deformation in these areas and concluded that it occurred between the late Paleozoic and the early Mesozoic. In addition, the locations of Wushan, Guanzizhen, Xinyang, Shetang, Yuanlong and Tangzang from west to east are close to each other and show spatial correlations. As the mafic and ultramafic rocks in Wushan and Guanzizhen belong to the Danfeng Complex, the deformation documented in the Wushan, Guanzizhen, Shetang, Xinyang, Yuanlong and Tangzang areas represents the deformation of the

SDTZ in western Qinling. Therefore, we think that the deformation along the SDTZ in western Qinling is a dextral strike-slip dominant deformation and occurred between ca.227-202Ma. The Xinyang-Yuanlong shear zone is a branch of the SDTZ in western Qinling.

4.6 Tectonic implications

4.6.1 The importance of the strike-slip deformation in the QOB

The current tectonic models of the QOB (e.g., Zhang et al., 2001; Dong et al., 2011a; Dong and Santosh, 2016) mainly use the concept of the Wilson cycle (Wilson, 1966) as a unifying conceptual framework and consider the orthogonal subductions and collisions among different tectonic plates. In this study, the predominant strike-slip deformation along the SDTZ is well established, which suggests that the non-coaxial deformation inside the QOB may have a demonstrably profound effect on the tectonic evolution and the current style (i.e., linear zonation) of the QOB.

As shown in van Staal et al.(1998), the forward modeling of the oblique collision between Australia and Asia will produce a linear orogen (Fig.4.20) due to the transpressional flattening and non-coaxial deformation during the ultimate collision. Fig.4.20a (Fig.5a in van Staal et al., 1998) is a simplified tectonic map of the west and southwest Pacific at present. Fig.4.20b (Fig.5b in van Staal et al., 1998) shows the configuration of this area after 45Ma produced by the collision of the Australian plate with the Asian plate along a broad zone of sinistral oblique convergence assuming a 55-million-year constancy of relative plate motions (van Staal et al., 1998). They (van Staal et al., 1998) use this model to test if ‘the superficial simple zonation and linearity’ of the Appalachian-Caledonide Orogen could be a result of terminal collisional

processes. The forward modeling result shows that the complexity of tectonic elements and an earlier complicated geometry may be obscured, and the broad zone results in a simple linear geometry because of the oblique convergence. The major effects of the oblique convergence that one should consider when trying to extrapolate the tectonic evolution of a linear orogenic belt are: 1) the tectonic units are transpressionally flattened, sheared and rotated into linear orogenic zones; 2) the final position and orientation of the tectonic elements after the ultimate collision may be quite different from the original paleogeographic position and orientation; 3) the once continuous tectonic element may be scattered and transported far away from each other during the final collision.

Figure 4.20 Forward modeling in van Staal et al. (1998). (a) The present-day tectonic configuration of the Australia-Asia area. (b) The interpretative plate configuration of the Australia-Asia collision 45Ma in the future (Fig.5 in van Staal et al., 1998).

Many ancient orogens, such as the Appalachian-Caledonide belt and the QOB, are strikingly linear or slightly arcuate over thousands of kilometers. The normal practice for the studies of these orogens is to draw zones and subzones that are featured by some tectonic elements in a linear manner along the great strike length. Namely, researchers try to ‘impose an along-strike correlative unity and continuity’ of the tectonic elements (van Staal et al., 1998). However, this simple linearity and zonation of an orogenic belt are in contrast with the complexity of modern convergent systems such as the west and southwest Pacific region in Fig.4.20a. The above forward modeling (Fig.4.20) shows that the linear configuration of the ancient orogens may result from the terminal collisional processes and the tectonic elements will experience profound spatial and geometric changes during this time.

Van Staal et al. (1998) applied the above lessons to the northern Appalachian-Caledonian belt and proposed a refined tectonic model for the evolution of the belt during the Cambrian to the Silurian. The above lessons should be considered in the tectonic evolution models of the QOB.

4.6.2 The tectonic configuration of the QOB before the Triassic

The fierce debate on the evolution of the QOB during the Paleozoic is focused on the precise location of the collisional zone. Some authors agree that the subduction and collision of the NCB and SCB were along the Shangdan suture zone with the Erlangping back-arc basin (e.g., Zhu, 2001; Xu et al., 2002; Dong et al., 2011a,b), while some authors argue that the major suture zone was marked by the Erlangping ophiolitic mélangé (Xue et al., 1996; Ratschbacher et al., 2003, 2006; Wang et al., 2011). According to a recent review paper (Dong and Santosh, 2016), the Erlangping

Complex is composed of basaltic rocks, andesites and rhyolites with a few ultramafic and clastic rocks. The rhyolites may suggest that the Erlangping Ocean experienced a back-arc rift and formed arc-related volcanic and E-MORB rocks (Dong and Santosh, 2016). The Danfeng Complex is composed of N-MORB, E-MORB and arc-related volcanic rocks without rhyolite (Zhang et al., 2001; Dong et al., 2011a,b; Dong and Santosh, 2016). Considering the petrology, geochemistry, regional scale of the Shangdan suture, the Shangdan suture is regarded as the major boundary during the Paleozoic. Therefore, the idea that the Shangdan suture was the major suture with the Erlangping back-arc basin during the Paleozoic is adopted here.

Reflecting the idea that the Shangdan suture was the major suture with the Erlangping back-arc basin, there are two dominant models regarding the evolution of the NQB. One is summarized in Dong and Santosh (2016) (Fig.4.21 left), and the other is in Liu et al. (2016) (Fig.4.21 right). The two major differences between these two models are: 1) the question of when the Shangdan ocean closed; 2) if the close of the Shangdan ocean led to the collision of the SCB and the NCB or the amalgamation of the SQB with the NCB.

In Liu et al.(2016), the model is mainly based on the high-pressure and ultra-high pressure (HP-UHP) rocks in the Qinling Complex. Liu et al.(2016) interpreted that the HP-UHP metamorphic age at ca.500Ma and retrograde metamorphic ages of ca.470-450Ma and ca.420-400Ma from the HP-UHP rocks can be related to the magmatic ages in the Qinling Complex (~500Ma, ~450Ma and ~420Ma) indicating deep subduction/collision, slab-breakoff and crustal thinning during post-collisional extension, respectively. However, this model conflicts with the provenance studies of

the fore-arc prism in the Heihe area (Dong et al., 2013a) and the Wuguan Complex in the Danfeng area (Yan et al., 2016). As the main proof of Liu et al.(2016)'s model was based on the metamorphic and magmatic ages and geochemical studies in the Qinling Complex, the data directly reflect the tectonic settings of the Qinling Complex but not the whole QOB. Especially, as the importance of the transcurrent movement among tectonic elements during an oblique convergence has been discussed in Section 6.3, the current connected tectonic elements may have been a great distance from each other before the terminal collision. Therefore, in our opinion, the model proposed by Liu et al. (2016) is not convincing.

Dong et al. (2013a) analyzed the detrital zircons from the fore-arc prism that is at the southern edge of the Shangdan Complex in Heihe. The detrital zircons show a uniform age spectrum of ca.455-600Ma that is only attributed to the NQB without any contribution from the SQB and the SCB, so the Shangdan ocean still existed at 455Ma (Dong et al., 2013a). Combined with the crystallization age of a diabase that is intruded into the fore-arc prism, the depositional age of the fore-arc prism is constrained to 455-435Ma. Yan et al. (2016) studied detrital zircons of the Wuguan Complex in the Danfeng area. The Wuguan Complex is to the southern side of the Shangdan Complex in the Danfeng area. The detrital zircons in the Wuguan Complex show an age spectrum with two major peaks at 453Ma and 800Ma and minor populations at 350-430Ma and 1000-2868Ma, and the weighted mean age of the youngest group is 358 ± 3 Ma (Yan et al., 2016). The age (358Ma) is related to the ages of 351Ma and 358Ma from andesites in the Shangdan and Fengxian areas (Chen, 2008; Chen et al., 2014). According to Yan et al. (2016), the geochemical characteristics of

the Wuguan Complex indicate that the sedimentary rocks were originally deposited at an active continental margin corresponding to the northward subduction of the Shangdan ocean, so the northward subduction may have still been active at 358Ma.

The fore-arc prism in the Heihe area and the Wuguan Complex in the Danfeng area are now cropped as lenses along the SDTZ, and both have been interpreted as the sedimentary units along an active margin corresponding to the northward subduction of the Shangdan ocean (Dong et al., 2013a; Yan et al., 2016). They are likely to be one sedimentary unit but transposed to current locations and shapes by later deformation.

The Liuling Group is south of the Wuguan Complex and the Shangdan Complex. The detrital zircons of the Liuling Group (Dong et al., 2013a; Liao et al., 2017) yield an age spectrum with major groups of 500-400Ma, 850-700Ma and 1000-900Ma and minor populations at 1750-1450Ma, 2000Ma and 2600-2400Ma, and the source rocks of the sediments are from both the NQB and the SQB. The depositional age of the Liuling Group is further constrained by a pegmatite intruded into the Liuling Group. The crystallization age of the pegmatite is 373.8Ma (Shi, 2016), so the depositional age of the Liuling Group is during 373.8-400Ma. As the source rocks of the Liuling Group are from both the NQB and the SQB, the Shangdan ocean was nearly closed during Devonian.

Figure 4.21 The comparison of the tectonic evolution models from Dong and Santosh (2016, left) and Liu et al. (2016, right) of the QOB during 600~400Ma.

As the youngest magmatic age in the NQB in the Paleozoic is ca.300Ma and it is I-type granitoid (Fig.13 in Wang et al., 2013), the subduction along the Shangdan suture may have ceased after 300Ma. However, there is a lack of the full collision between the NQB and the SQB (Dong and Santosh, 2016).

4.6.3 Tectonic model of the QOB during Triassic

The Mesozoic Mianlue suture is between the SCB and the SQB and marked by a series of ophiolitic mélangé, oceanic island and island-arc volcanic rocks (Zhang et al., 2001, 2015; Dong et al., 2011a; Dong and Santosh, 2016). The Triassic northward subduction and collision led to the final amalgamation of the NCB and the SCB and produced syn- and post-collisional granitoids in the SQB with ages of 245-200Ma (Dong et al., 2011a; Dong and Santosh, 2016).

In this thesis, the dominant strike-slip deformation along the SDTZ occurred at the late Triassic in the QOB is recognized. However, the late Triassic strike-slip deformation along the SDTZ show opposite kinematic senses in western Qinling (this chapter) and eastern Qinling (Chapter 3) that are separated by the narrowest segment in the SQB. In addition, the deformation along the Mianlue suture in western Qinling shows a sinistral sense of shear. The deformation age is constrained by a muscovite $^{40}\text{Ar}/^{39}\text{Ar}$ age (223Ma, Chen et al., 2010).

The tectonic evolution of the QOB during Triassic is proposed in Fig.4.22. Around 250Ma (Fig.4.22a), the Mianlue oceanic crust subducted under the SQB resulting in subduction-related volcanic rocks that are reported in the SQB (Wang et al., 2013). The subduction led to the gradual consumption of the oceanic crust

(Fig.4.22b), and the sediments of the Triassic Songpan-ganzi Complex came from both the SCB and the SQB (Enkelmann et al., 2007). According to the simulation results in Chapter 3, the convergence angle was in the range of $20^{\circ} \sim 40^{\circ}$. The Paleozoic Shangdan suture was acting as a weak inclusion in the QOB and accommodating strike-slip deformation in response to the oblique convergence. The voluminous granitoids ranging of ca.220-210Ma may reflect the collision between the SCB and the SQB. This model consists with the tectonic model proposed by Li et al. (2017) that is deduced from the syn-tectonic emplacement of the Baliping pluton in eastern Qinling during the Triassic. To the west (present coordinate) of the SQB, there might be some remnants of the Paleo-Tethys ocean so that the western Qinling and the Songpan-ganzi Complex had enough space to extrude to the west (Fig.4.22c). According to the results in this chapter and Chapter 3, the strike-slip deformation along the SDTZ may continue to ca.201Ma. The final collision between the SCB and the SQB led to the final amalgamation of the SCB and the NCB and produced the dramatic Dabashan thrust system and shortening structures in the SQB. According to Dong et al. (2013b), the Dabashan thrusting was active until the late Jurassic (ca.165Ma) in response to the convergence of the NCB and the SCB.

Figure 4.22 Schematic cartoons showing the tectonic evolution of the Qinling orogenic belt during the Triassic. NCB: North China Block, NQB: North Qinling Belt, SQB: South Qinling Belt, SCB: South China Block; SDS: Shangdan suture, MLS: Mianlue suture. Detailed explanation referred to the text.

4.6.4 The Cretaceous E-W extension recorded in the Liuling Group

The recumbent folds and the L-tectonites in the Liuling Group indicates an E-W extension and vertical thinning kinematic feature. The orogen-scale L-tectonites in the Tongbai orogenic belt can be correlated to this deformation in the Liuling Group according to the similar geometry and the locations (detailed discussion can be found in Section 3.4.2). As the L-tectonites in the Tongbai orogenic belt was developed between 140-135Ma (Liu et al., 2017), this deformation in the Liuling Group occurred during the same time, and they both reflect the early Cretaceous E-W extensional event in the Central China Orogenic Belt (CCOB).

However, this deformation is only observed in the Liuling Group in eastern Qinling but not found in western Qinling, which may indicate that the extension was not uniform throughout the whole orogen and it was more intense in the eastern part but weaker in the western part. This phenomenon is probably because, during the early Cretaceous, the Pacific Ocean was east (present coordinate) of the CCOB (Matthews et al., 2016) so that there was more space for the orogen to extrude to the east. This extension event may hold responsible for the formation of the Nanyang basin and the coeval magmatism in the eastern CCOB (Fig.4.23).

Figure 4.23 Geological map showing Neoproterozoic, Early Paleozoic, Late Triassic and Cretaceous magmatic intrusions in the Qinling orogenic belt (modified after Dong and Santosh, 2016).

Chapter 5: Conclusions and Future Work

In this thesis, the detailed field work is conducted along the Shangdan tectonic zone (SDTZ) in the Qinling orogenic belt (QOB), China. The multiscale structures along the SDTZ is documented and analyzed. With the help of the recently-developed multiscale approach and the geochronological studies, we try to understand the tectonic evolution and kinematics of the SDTZ and its implications for the Qinling tectonics.

5.1 Contribution of this work

The multiscale approach used in this thesis is called the multi-order power-law approach (MOPLA) (Jiang and Bentley, 2012; Jiang, 2014). MOPLA is developed to study the heterogenous deformation throughout Earth's lithosphere. The heterogenous deformation results from the rheological heterogeneities of the lithosphere (Lister and Williams, 1979, 1983), and MOPLA treats a heterogeneous material as a continuum of rheologically distinct elements. The rheological properties of the material and the mechanical fields of each constituent element are computed by solving the partitioning and homogenization equations self-consistently. The algorithm is based on the solution of an Eshelby viscous inclusion in a linear viscous medium and the extension of the solution to non-linear viscous materials (Jiang and Bentley, 2012; Jiang 2014, 2016). The bottleneck of the computation is to numerically evaluate Eshelby tensors for the constituent elements. In this thesis, we develop an optimal scheme for evaluating Eshelby tensors, using a combination of a product Gaussian quadrature and

the Lebedev quadrature. We first establish, through numerical experiments, an empirical relationship between the inclusion shape and the computational time it takes to evaluate its Eshelby tensors. We then use the relationship to develop an optimal scheme for selecting the most efficient quadrature to obtain the Eshelby tensors. This optimal scheme is adopted into MOPLA. Currently, MOPLA is fully developed into MATLAB and Mathcad.

This work shows the importance of the structural geology studies to the tectonic evolution of an orogenic belt. The previous work in the QOB is mainly focused on the framework of the evolution of the QOB (e.g., Zhang et al., 2001; Ratschbacher et al., 2003, 2006; Bader et al., 2013a,b; Dong and Santosh, 2016), but the detailed kinematics of the orogen and the various structures in the orogen are not related to the tectonic evolution precisely, which is mainly because of the lack of detailed structural geology studies in the QOB.

In this thesis, three deformation events are identified in the SDTZ and its adjacent areas. They are labeled as D_1 deformation, D_2 deformation and D_3 deformation, respectively. D_1 deformation is a NE-SW (to the current coordinate system) shortening deformation and occurred between ca.385-355Ma. D_1 deformation is only observed to the north of the SDTZ in western Qinling. D_2 deformation is a strike-slip dominant deformation and occurred between ca.227-201Ma. In western Qinling, D_2 deformation is a dextral strike-slip along the SDTZ; In eastern Qinling, D_2 deformation is a sinistral strike-slip along the SDTZ and N-S (to the current coordinate system) shortening deformation in the Liuling Group that is south of the SDTZ. D_3

deformation is an along-orogen extension and occurred between ca.140-135Ma. D₃ deformation is only observed in the Liuling Group in eastern Qinling.

D₂ deformation, the opposite shearing along the SDTZ and the N-S (to the current coordinate system) shortening deformation in the Liuling Group, was a response to the oblique convergence between the South China Block and the North China Block. The convergence angle is constrained to 20°~40° using MOPLA.

In this thesis, predominant strike-slip along the SDTZ is clearly established, which suggests that the non-coaxial deformation inside the QOB have a demonstrably profound effect on the tectonic evolution and the current style (i.e., linear zonation) of the QOB (see discussions in Section 4.6.1 for detail). In previous Qinling models, the orthogonal subductions and collisions among different tectonic blocks are mainly considered. The geological units can be highly transposed during an oblique convergence, so the once continuous element may be scattered and far away from each other during the final convergence. This ‘dynamic’ idea should be adopted in the future studies of the QOB.

5.2 Future work

The strike-slip deformation time along the SDTZ in western Qinling is constrained by the age of a syn-deformation dyke (i.e., XY1605). However, there is only one analysis (Spot No.10 in XY1605, Fig.E12). More zircons from XY1605 will be analyzed for a better constrain of the crystallization age of this dyke.

In Fig.4.22, a tectonic model is proposed to explain the opposite shearing along the SDTZ. According to the model, the western Qinling was extruding to the west

which resulted in the dextral strike-slip deformation along the SDTZ in western Qinling. In this case, there would be an along-strike extension component in the boundary condition of the SDTZ. However, in Jiang (2014), only the transpressional condition that does not include an along-strike stretching component has been considered. Therefore, to better constrain the boundary conditions of the fabrics in the SDTZ in western Qinling, more boundary conditions need to be tested.

According to the tectonic model in Fig.4.22, the neck area (i.e., the narrowest segment in the SQB) would show very interesting structures, and thus more field work will be conducted in this area.

Appendices

Appendix A: Empirical functions for the domain boundaries in Fig.2.4

According to the computational time contours in Fig.3.3, we use MATLAB built-in function, *fit*, to empirically construct four curves: $R = f_1(\Phi)$ (computational time $\sim 3s$), $R = f_2(\Phi)$ (computational time $\sim 15s$), $R = f_3(\Phi)$ (computational time $\sim 30s$), $R = f_4(\Phi)$ (computational time $\sim 40s$).

The expressions of the four curves are as follows:

$$R_1 = -1.944 \times 10^{-8} \Phi^4 - 4.289 \times 10^{-6} \Phi^3 + 1.325 \times 10^{-3} \Phi^2 - 0.0958 \Phi + 2.552 \quad (A1)$$

$$R_2 = 1.025 \times 10^{-8} \Phi^4 - 2.461 \times 10^{-6} \Phi^3 + 6.203 \times 10^{-4} \Phi^2 - 0.06954 \Phi + 4.018 \quad (A2)$$

$$R_3 = 1.496 \times 10^{-7} \Phi^4 - 2.729 \times 10^{-5} \Phi^3 + 1.792 \times 10^{-3} \Phi^2 - 0.07242 \Phi + 4.583 \quad (A3)$$

$$R_4 = 3.693 + 0.7857 \cos(0.05009\Phi) + 0.4061 \sin(0.05009\Phi) + 0.1859 \cos(2 \times 0.05009\Phi) - 0.09161 \sin(2 \times 0.05009\Phi) + 0.08343 \cos(3 \times 0.05009\Phi) - 0.02982 \sin(3 \times 0.05009\Phi) \quad (A4)$$

Appendix B: The MATLAB package instruction in Chapter 2

The MATLAB package can be downloaded from the online version of this paper.

1. Before executing the four functions (i.e., *SGLRGD*, *SGLDEF*, *MLTRGD*, *MLTDEF*), one needs to add all folders and subfolders to the current path in MATLAB.

2. Input parameters for each function are as follows:

1) *SGLRGD*

L is the imposed velocity gradient tensor, a 3 by 3 matrix;

a is the three semi-axes of the ellipsoid, a 3 by 1 matrix;

ang is the three spherical angles (in degree), a 3 by 1 matrix;

tincr is the time increment, the choice of *tincr* must ensure that each step of computation represents an infinitesimal rotation;

steps is the total computational steps;

mm is the number of computation steps between plotting sets;

m is the anisotropy for the matrix.

2) *SGLDEF*

Besides the 7 parameters introduced in *SGLRGD*, the other 4 parameters are:

Nm is the stress exponent of the matrix;

Ne is the stress exponent of the ellipsoid;

r is the initial ratio of the inclusion viscosity to the matrix η_n ;

REF is an initial effective viscosity of the ellipsoid.

3) *MLTRGD*

L , $tincr$, $steps$, m are as same as those in *SGLRGD*, and

n is the number of ellipsoids;

a_1 the maximum semi-axis of ellipsoids;

4) *MLTDEF*

L , $tincr$, $steps$, m , Nm , Ne are as same as those in *MLTRGD* and

SGLDEF, and

$rmax$ and $rmin$ define the range of viscosity ratio between the ellipsoids and the matrix at the initial state.

One may refer to the “*ReadMe.txt*” and comment lines in the package for more detailed descriptions.

Appendix E: The geochronological results in Chapter 4.

The analytical data from the Yuanlong, Shetang and Xinyang areas are in Table E1, Table E2 and Table E3, respectively. Rare-earth element (REE) contents are in Table E4, Table E5 and Table E6, respectively.

1. Results from the Yuanlong area

(1) TS1406

The size of zircons from TS1406 is in the range of 80 μ m~150 μ m (Fig.E1a). They are subhedral to euhedral prismatic with length-to-width ratios ranging from 1.5 to 4. Some of the zircons (Spot No.03, 10, 11, 13, 14, 16, 20-23, 26, 32) show no zoning, and others exhibit well-developed or relatively weak oscillatory zoning that is a dominant feature of igneous rocks. Spot No.02, 04, 05, 08, 09, 11, 12, 15, 17, 18, 21, 24, 25, 27, 29-31, 33, 34 are xenocrystic cores.

Spot No.01, 02, 09, 19 have Th/U ratios > 0.5 , which probably indicates a magmatic origin. Spot No.13, 16, 22 and 26 have Th/U ratios < 0.1 indicating completely recrystallized zircon (Hoskin and Schaltegger, 2003).

Most zircons show REE patterns with a positive Ce-anomaly and negative Eu-anomaly with a steeply-rising slope from the LREE to the HREE and have less LREE abundances (Fig.E1b), except for Spot No.03, 05, 06, 13, 16, 17, 18 and 22 (Fig.E1c). Spot No.03, 05, 06, 13 and 17 have high LREE and MREE abundances, so the slope from LREE to HREE is shallow, and they do not show clearly negative Eu-anomaly. Spot No. 18 shows a positive La-anomaly instead of a Ce-anomaly, and Spot No.22

exhibits a positive Ce-anomaly as well as a positive Pr-anomaly. Spot No.16 has no positive Ce-anomaly, and all LREE are depleted. As Spot No.03, 05, 06, 13, 16, 17, 18 and 22 show REE patterns that differ from the typical REE pattern of unaltered igneous zircon, they were affected by later processes or completely recrystallized.

Table E1 LA-ICP-MS U-Pb zircon dating results of the samples from the Yuanlong area.

Spot No.	Th(ppm)	U(ppm)	Th/U	Isotope ratios								Ages(Ma)								Disc.%

According to the CL images, Th/U ratios and REE patterns, the zircons that are suspiciously not from a magmatic origin or affected by later processes are Spot No.03, 05, 06, 10, 11, 13, 14, 16-18, 20-23, 26, 32. Among all these zircons, Spot No.10, 11, 20-23, 26, 32 display concordant ages (disc.% < $\pm 10\%$).

The Th/U ratio of Spot No.22 is 0.02, and its REE pattern is not a typical unaltered igneous zircon, and most importantly, Spot No.22 is a dark zircon like Spot No.10, 20, 23 and 26, 32. In the case that the domains are homogeneously dark in CL, they are considered as no zoning, and the low luminescence may be caused by high trace-element contents or by metamictization or by high-pressure metamorphism (Corfu et al., 2003). These analyses are grouped into metamorphic ages. Spot No.11&21 are xenocrystic cores with dark overgrowth rims. As the zoning in Spot No.11&21 is blurred, the age U-Pb age is reset due to the recrystallization (Hoskin and Schaltegger, 2003). These analyses are considered to reflect metamorphism. The metamorphic ages fall into several groups: 805.9 ± 7.11 Ma (1 analysis, Spot No.11); 493 ± 4.56 Ma (1 analysis, Spot No.10); $443.2 \sim 438.6$ Ma (4 analyses, Spot No.20, 21, 23, 26); $424.2 \sim 428$ Ma (2 analyses, Spot No.22, 23).

Other concordant ages are interpreted as magmatic ages, and can be divided into several groups: 952 ± 8.41 Ma (1 analysis, Spot No.15); $472.4 \sim 470.3$ Ma (3 analyses, Spot No.29, 35, 36); $440 \sim 431.5$ Ma (6 analyses, Spot No.08, 12, 25, 30, 31, 34); $428 \sim 418.9$ Ma (6 analyses, Spot No.02, 04, 07, 19, 27, 33); 402.1 ± 3.53 Ma (1 analysis, Spot No.01); 387.6 ± 3.62 Ma (1 analysis, Spot No.28). The youngest age group (although only one analysis) may indicate the crystallization age of the dyke, and the age is 387.6 ± 3.62 Ma.

(a)

Figure E1 CL images and the REE pattern of TS1406.

(2) TS1408-1

Zircon grains range from 30 μ m to 150 μ m in TS1408-1. Some zircons are ellipsoidal or rounded shapes (Spot No.03, 07, 08, 16, 24, 28, 30, 31, 32 and 33), and

others are subhedral to euhedral prismatic with length-to-width ratios ranging from 1.5 to 2.5. Most of the zircons show a medium-luminescent core with a low-luminescent rim (e.g., Spot No.05, 07, 08, Fig.E2a). Unfortunately, the rims are too thin to be measured. Most xenocrystic cores exhibit well-developed zoning, except for Spot No.03, 10, 16, 31. Spot No.06, 14, 17 and 36 are homogeneously dark with no zoning.

Th/U ratios are in the range of 0.13~1.14. Spot No.08, 13, 19, 20, 22, 27 have Th/U ratios > 0.5.

Most of the zircons have REE patterns showing a positive Ce-anomaly and negative Eu-anomaly and a steeply rising from LREE to HREE (Fig.E2b), while Spot No.09, 13, 24, 27, 31 and 32 show different patterns (Fig.E2c). Spot No.13, 31 and 32 are relatively abundant in LREE, and Spot No. 09 and 27 are abundant in Ce and Pr as well as no negative Eu-anomaly, and Spot No.24 does not show positive Ce-anomaly.

According to external morphology, internal texture, Th/U ratio and REE pattern, the analyzed spots that are suspected not to be magmatic origin are Spot No.03, 06, 09, 10, 13, 14, 16, 17, 24, 27, 31, 36. As Spot No.09&16 show discordant ages (disc.%=23.6%-12.0%), we do not discuss these two analyses further.

Spot No.03, 10, 13, 16, 24 and 31 are xenocrystic cores, and the primary igneous oscillatory zoning is blurred. The blurred primary zoning is an indication of the metamorphic disturbance (Hoskin and Schaltegger, 2003), so their ages are interpreted as metamorphic ages. Spot No.06, 14, 17, 27 and 36 are homogenous dark zircons, and some of them even contain darker domains. This characteristic may be related to metamorphism, so these ages are interpreted as metamorphic ages. The

metamorphic ages fall into distinct groups: $1107.4 \pm 9.75\text{Ma}$ (1 analysis, Spot No.13); $959.9 \pm 8.47\text{Ma}$ (1 analysis, Spot No.31); $916.8 \sim 894.5\text{Ma}$ (2 analyses, Spot No.09, 24); $829 \pm 7.69\text{Ma}$ (1 analysis, Spot No.03); $444 \sim 425.3\text{Ma}$ (4 analyses, Spot No.14, 17, 27, 36).

Excluding the metamorphic ages and discordant ages, the magmatic ages can be grouped into several sets: $1469.6 \pm 13.1\text{Ma}$ (1 analysis, Spot No.20); $1355.3 \pm 11.98\text{Ma}$ (1 analysis, Spot No.08); $1131.9 \sim 1066.3\text{Ma}$ (2 analyses, Spot No.30, 35); $994.4 \sim 973.3\text{Ma}$ (4 analyses, Spot No.28, 29, 33, 34); $946.7 \sim 904.1\text{Ma}$ (5 analyses, Spot No.04, 05, 15, 22, 23); $884.5 \sim 867.5\text{Ma}$ (3 analyses, Spot No.01, 07, 11); $505 \pm 4.9\text{Ma}$ (1 analysis, Spot No.25); $455.2 \sim 424.8\text{Ma}$ (4 analyses, Spot No.06, 18, 19, 26); $393.3 \sim 392.3\text{Ma}$ (2 analyses, Spot No.02, 12). The weighted mean age of the youngest group is $392.8 \pm 4.9\text{Ma}$ (MSWD=0.041) and may indicate the crystallization age of this dyke.

Figure E2 CL images and the REE pattern of TS1408-1.

(3) TS1408-2

The size of zircon grains is from 30 μ m to 100 μ m. Some zircons (e.g., Spot No.01, 02, 05) are subhedral to euhedral prismatic with length-to-width ratios ranging

from 1.5 to 4, and some are rounded in shape (e.g., Spot No.21, 28, 30). Most of the zircons preserve xenocrystic magmatic cores with dark overgrowth rims (e.g., Spot No.02, 07, 08). The analyzed spots that exhibit magmatic oscillatory zoning are Spot No.01-10, 12-14, 17, 18, 20-24, 26-28, 30, 32 (Fig.E3a). Namely, according to the CL imaging, the analyzed spots that are not magmatic zircons are Spot No.11, 15, 16, 19, 25, 29, 31, 33-36.

Th/U ratios are between 0.01 and 0.64. Spot No.19, 31, 34 and 35 have Th/U ratios < 0.1 which may indicate a metamorphic origin.

Most analyses show a featured magmatic REE pattern with a steeply rising from LREE to HREE, a positive Ce-anomaly, and a negative Eu-anomaly, except Spot No.03, 15, 33, and 34 (Figs.E3b,c). Spot No.03, 15, 33 and 34 all show negative Eu-anomalies. Spot No. 03 and 33 are abundant in LREE, Spot No.15 is abundant in Ce and Pr, and Spot No.24 shows a negative Ce-anomaly.

Among all analyses, Spot No.03, 04, 29 and 33 show discordant ages, and will not be discussed further. According to CL imaging, Th/U ratio and REE pattern, analyzed spots that are considered as metamorphic ages are Spot No.11, 15, 16, 19, 25, 31, 34-36. These ages fall into several groups: $1704.8 \pm 38.32\text{Ma}$ (1 analysis, Spot No.25); $916 \sim 896.6\text{Ma}$ (2 analyses, Spot No.11, 15); $461.4 \sim 446.7\text{Ma}$ (4 analyses, Spot No.19, 31, 35, 36); $439.2 \pm 3.94\text{Ma}$ (1 analysis, Spot No.34); $384.7 \pm 3.3\text{Ma}$ (1 analysis, Spot No.16).

The magmatic ages can be divided into distinct groups: $1236.6 \sim 1090.2\text{Ma}$ (4 analyses, Spot No.07, 18, 28, 30); $969 \sim 951.5\text{Ma}$ (4 analyses, Spot No.09, 10, 23, 26);

938.5~932.6Ma (2 analyses, Spot No.14, 21); 918~898.1Ma (2 analyses, Spot No.02, 08); 474.3±4.34Ma (1 analysis, Spot No.27); 458.3~443.3Ma (4 analyses, Spot No.05, 17, 22, 32); 439.1~423.3Ma (6 analyses, Spot No.01, 06, 12, 13, 20, 24). The weighted mean age of the youngest group is 430.9±5.8Ma (MSWD=2.1) and indicate the crystallization age of this dyke.

Figure E3 CL images and the REE pattern of TS1408-2.

2. Results from the Shetang area

(1) ST1502

CL images of analyzed zircons from ST1502 are in Fig.E4a. Most zircons are fragments of zircon grains. Even though they are fragments, the diameters of them are

about 200 μm , so they are extremely large zircon grains. Most of the zircons show magmatic oscillatory zoning structures and medium to less luminescent. Spot No.04, 06, 16, 18, 20 and 27 show homogenous dark or grey domains that may result from metamorphism.

The Th/U ratios of these analyzed spots are in the range of 0.008~1.255. Spot No.03, 11, 22, 28 and 33 have Th/U ratios < 0.1 .

Most of the analyzed spots show typical igneous REE pattern (Fig.E4b) with a positive Ce-anomaly, a negative Eu-anomaly and a steeply rising from LREE to HREE. Spot No.03, 07, 22 and 27 show different patterns. Spot No.03&07 do not show negative Eu-anomaly, and Spot No.07&27 are abundant in LREE (Fig.E4c).

Based on the features of CL image, Th/U ratio and REE pattern, the spots that are not magmatic origin are Spot No.03, 04, 06, 07, 11, 16, 18, 20, 22, 27, 28, 33. Among them, Spot No. 06&07 display discordant ages. Other metamorphic ages fall into distinct groups: 2488~2406.8Ma (4 analyses, Spot No.04, 18, 20, 27); 2173.2~2005.1Ma (2 analyses, Spot No.16, 22); 1890.1~1708.8Ma (4 analyses, Spot No.03, 11, 28, 33).

The magmatic zircons with concordant ages fall into several groups: 2514.6~2304.5Ma (20 analyses, Spot No.01, 02, 09, 10, 12-15, 17, 19, 23-26, 29-32, 34, 35); 2262.9~2254.4Ma (2 analyses, Spot No.15, 21); $1982 \pm 39.79\text{Ma}$ (1 analysis, Spot No.08). They are all xenocrystic ages.

Figure E4 CL images and the REE pattern of ST1502.

(2) ST1510-1

Zircon grains from ST1510-1 are large, and the size is in the range of 150~250 μm (Fig.E5a). Most of them are subhedral to euhedral prismatic with length-to-width

ratios ranging from 1.5 to 4. Most of the zircons show well-developed magmatic oscillatory zoning structures, and Spot No.01, 21 show typical magmatic sector zoning structures. Many of the grains show a magmatic core with a dark rim (Spot No.02, 05, 09, 10, 11, 12, 13&14, 15, 16, 27&28, 30, 31 and 33). Unfortunately, most of the rims are too thin to be measured. Only one dark rim is analyzed (Spot No.28), and its $^{207}\text{Pb}/^{206}\text{Pb}$ age is $2230.1 \pm 37.45\text{Ma}$ (disc.% = -30.9%). Instead of a dark rim, one grain shows a magmatic overgrowth (Spot No. 34&35) and one grain shows a weakly zoning rim with high luminescent (Spot No.26). Some zircons show no igneous oscillatory zoning (Spot No.04, 20, 24, 26, 31 and 32), and they may be metamorphic zircons.

The Th/U ratios range from 0.10 to 0.75.

Most REE patterns (Fig.E5b) show positive Ce-anomalies, negative Eu-anomalies and steeply-rising slopes from LERR to HERR, except for Spot No.05, 07, 09, 13, 34. Spot No.05&34 do not show negative Eu-anomaly, and Spot 07, 09, 13 are relatively abundant in LREE, especially, Spot No.13 (Fig.E5c).

In summary, the analyzed spots that may reflect metamorphic ages are Spot No.04, 05, 07, 09, 13, 20, 24, 26, 31-34. Spot No.26 is not concordant. The other metamorphic ages can be divided into the following groups: $2623.6 \pm 35.13\text{Ma}$ (1 analysis, Spot No.34); $2415.3 \sim 2352.1\text{Ma}$ (4 analyses, Spot No.05, 13, 20, 31); $2175.7 \pm 36.68\text{Ma}$ (1 analysis, Spot No.07); $1907.9 \sim 1821.9\text{Ma}$ (3 analysis, Spot No.09, 24, 33); $1753 \sim 1697.2\text{Ma}$ (2 analyses, Spot No.04, 32).

Figure E5 CL images and the REE pattern of ST1510-1.

The magmatic concordant ages can be grouped into distinct sets: $2639.8 \pm 33.67\text{Ma}$ (1 analysis, Spot No.21); $2430.7 \sim 2313.2\text{Ma}$ (8 analyses, Spot No.01, 08, 11, 14, 19, 23, 25, 29); $2193.4 \pm 40.56\text{Ma}$ (1 analysis, Spot No.17); $2095.7 \sim 2064\text{Ma}$ (2 analyses, Spot No.15, 17); $2031.6 \sim 1805.7\text{Ma}$ (6 analyses, Spot No.12, 16, 18, 22, 30, 35); $1788.7 \sim 1669.9\text{Ma}$ (3 analyses, Spot No.02, 06, 10). They are all xenocrystic ages.

(3) ST1510-2

Zircon grains (Fig.E6a) from ST1510-2 are 100~220 μm in size, and most of the grains are subhedral to euhedral prismatic with length-to-width ratios ranging from 1.5 to 4. Spot No.18, 27, 31 show rounded shapes. Most of them show a magmatic core with an extremely thin dark rim. The cores display well-developed igneous oscillatory zoning structures, and some of them show sector zoning structures. Spot No.05, 10, 12, 13, 18, 22, 26 and 34 show blurred primary zoning.

Th/U ratios are in the range of 0.10~0.66.

No.02, 17, 18 show REE patterns that differ from a typical igneous REE pattern. Spot No.02&18 are relatively abundant in LREE, and Spot No.17 is extremely abundant in LREE even close to HREE (Fig.E6c).

The spots that may reflect metamorphism are No.02, 05, 10, 12, 13, 17, 18, 22, 26 and 34. They fall into two groups: 1005~896.9Ma (2 analyses, Spot No.17, 34); 888.6~853.9Ma (8 analyses, Spot No.02, 05, 10, 12, 13, 18, 22, 26).

The concordant magmatic ages fall into several groups: $2272.4 \pm 35.24\text{Ma}$ (1 analysis, Spot No.19); 1020.6~1008Ma (5 analyses, Spot No.03, 07, 25, 29, 31); 996.5~868.5Ma (17 analyses, Spot No.04, 06, 08, 09, 11, 14-16, 20, 21, 23, 24, 28, 30, 32, 33, 35); $831.7 \pm 8.99\text{Ma}$ (1 analysis, Spot No.27). They are all xenocrystic ages.

Figure E6 CL images and the REE pattern of ST1510-2.

(4) ST1511

The size of zircons in ST1511 is between 80 μ m and 200 μ m (Fig.E7a). Most of the grains are subhedral to euhedral prismatic with length-to-width ratios ranging from 1.5 to 3, and Spot No.17, 21, 22, 25-27 show rounded shapes. Most of the zircons show well-developed igneous oscillatory zoning and sector zoning structures. Some

show blurred zoning or homogenous domain which may indicate metamorphic effect (Spot No.03, 12, 15, 16, 22, 24, 25, 31, 35).

Th/U ratios are in the range of 0.11~1.28. Spot No.18&27 have Th/U ratios > 1.

REE patterns of Spot No.02, 07, 08, 10-14, 17, 18, 21, 22, 26, 28, 29, 33 and 34 consist with the classical igneous REE pattern: a positive Ce-anomaly, a negative Eu-anomaly and a steeply rising slope from LREE to HREE (Fig.E7b). REE patterns of Spot No.01, 03-06, 09, 15, 16, 19, 24, 29, 30-32, 35 show the relative depletion of HREE resulting in shallower slopes. Spot No.25 shows abundance in Ce and Pr, and Spot No. 23&27 are relatively abundant in LREE (Fig.E7c).

The spots that may indicate metamorphic ages are Spot No.01, 03-06, 09, 12, 15, 16, 19, 23-25, 27, 29, 30-32, 35. Among them, the spots that yield concordant ages are Spot No.03-06, 09, 19, 25, 29, 30, 32, 35. They fall into several groups: $860 \pm 8.89\text{Ma}$ (1 analysis, Spot No.25); $832.7 \pm 11.34\text{Ma}$ (1 analysis, Spot No.29); $434.2 \sim 421.6\text{Ma}$ (9 analyses, Spot No.03-06, 09, 19, 25, 29, 30, 32, 35).

The concordant magmatic ages fall into following groups: $1507.3 \pm 15.75\text{Ma}$ (1 analysis, Spot No.34); $1364.8 \pm 13.76\text{Ma}$ (1 analysis, Spot No.26); $1045.8 \sim 1044\text{Ma}$ (2 analyses, Spot No.10, 28); $980.3 \sim 942\text{Ma}$ (4 analyses, Spot No.02, 18, 21, 22); $718.5 \pm 8.15\text{Ma}$ (1 analysis, Spot No.11); $428.9 \sim 420.5\text{Ma}$ (3 analyses, Spot No.14, 24, 33). The weighted mean age of the youngest group is $423.4 \pm 5.6\text{Ma}$ (MSWD=0.72) and may indicate the crystallization age of this dyke.

Figure E7 CL images and the REE pattern of ST1511.

(5) ST1515

The size of zircons in ST1515 ranges from 100 to 220 μm (Fig.E8a). Some of them show euhedral prismatic with length-to-width ratios ranging from 1.5 to 4 (e.g., Spot No.01, 12, 13, 21, 22), some are fragments (e.g., Spot No. 05, 09, 17), and some show rounded shapes (e.g., Spot No.04, 11, 15). Many of them show no or weak zoning structures, and several show oscillatory clearly zoning structures (Spot No.11, 12, 14, 21, 22, 25, 32-35). Namely, Spot No.01-10, 13, 15-20, 23, 24, 26-31 may reflect metamorphism.

Th/U ratios of all analyzed spots in ST1515 are in the range of 0.04~0.44. Spot No.01-10, 12, 15, 17, 18, 21-24, 26-28, 30, 32 and 34 have Th/U ratios < 0.1.

Spot No.02, 05-11, 14-17, 19, 25-28, 30, 31, 33, 34 show REE patterns that are characterized by positive Ce-anomalies, negative Eu-anomalies and steeply rising slopes from LREE to HREE (Fig.E8b). Spot No.01, 03, 04, 12, 13, 18, 20-24, 29, 32, 35 show different patterns. Spot No.03, 04, 12, 18, 20-24, 29 and 35 are abundant in both Ce and Pr, and Spot No. 01 and 13 are relatively abundant in La and Ce, and Spot No. 32 is abundant in Pr but not Ce (Fig.E8c).

There are many metamorphic ages in this sample. They are Spot No.01-10, 12, 13, 15-24, 26-32, 34, 35. Excluding the discordant ages, the remaining ages fall into the following groups: 863.8~846.9Ma (4 analyses, Spot No.13, 16, 29, 31); 775.1 \pm 8.96Ma (1 analysis, Spot No.35); 444.5~442.7Ma (2 analyses, Spot No.01, 23); 412.8~381.2Ma (18 analyses, Spot No.02, 04-10, 15, 17, 19, 24, 26-28, 30, 32, 34); 343.6 \pm 3.75Ma (1 analysis, Spot No.22).

There are only four magmatic ages, and they fall into three groups:
871.2~870.2Ma (2 analyses, Spot No.14, 33); 770.7 \pm 8.25Ma (1 analysis, Spot No.11);
391.3 \pm 4.21Ma (1 analysis, Spot No.33). The youngest age may indicate the
crystallization age of this dyke (i.e., 391.3 \pm 4.21Ma).

(a)

Figure E8 CL images and the REE pattern of ST1515.

(6) ST1512

The longest dimension of the zircon grains in ST1512 ranges from 50 μ m to 200 μ m (Fig.E9a). Some of them show subhedral to euhedral prismatic with length-to-width ratios ranging from 1.5 to 4 (e.g., Spot No.01, 04, 05, 10), and some are rounded

in shape (e.g., Spot No.08, 24, 35). Some of them show well-developed igneous oscillatory zoning structures, and others show blurred zoning or homogenous domain (Spot No.04, 06, 08, 09, 13, 15, 17, 27, 35).

Th/U ratios are in the range of 0.13~0.95.

Most REE patterns are consistent with the typical igneous zircon showing a steeply rising from LREE to HREE, a positive Ce-anomaly and a negative Eu-anomaly (Fig.E9b). Spot No.33 shows a drop from MREE to HREE, and Spot No.08, 17, 20 are relatively abundant in LREE (Fig.E9c).

Figure E9 CL images and the REE pattern of ST1512.

The concordant metamorphic ages can be divided into the following groups:

1157 \pm 13.53Ma (1 analysis, Spot No.15); 956.4 \pm 10.08Ma (1 analysis, Spot No.35);

428.9~421.3Ma (2 analyses, Spot No.20, 33); 408.8 \pm 6.67Ma (1 analysis, Spot No.13).

The concordant magmatic ages fall into three groups: $950 \pm 13.18\text{Ma}$ (1 analysis, Spot No.18); $440 \pm 7.53\text{Ma}$ (1 analysis, Spot No.25); $429 \sim 416\text{Ma}$ (21 analyses, Spot No.01, 02, 04, 05, 07, 11, 12, 14, 16, 19, 22-24, 26, 28-32, 34).

(7) ST1513

Zircons from ST1513 vary in size. The longest dimension ranges from $30\mu\text{m}$ to $200\mu\text{m}$ (Fig.E10a). Most of them are subhedral to euhedral prismatic in shape, and the length-to-width ratio ranges from 1.5 to 4.5, and others are either fragments (e.g., Spot No.04, 12) or rounded in shape (e.g., Spot No.05, 13). About half of them show igneous oscillatory zoning structures, and others show no or weakly zoned characteristic (Spot No.03-05, 07, 10-13, 15, 17-20, 23, 30, 33, 35).

The Th/U ratio ranges from 0.02 to 1.48. Spot No.12, 20, 23 have Th/U ratios < 0.1 .

Spot No.02, 10, 15, 23 show abnormal REE patterns. Spot No.02, 10, 15 are relatively abundant in LREE, and Spot No.23 is relatively depleted in HREE (Figs.E10b,c).

In summary, the analyzed spots that may reflect metamorphism are Spot No.02-05, 07, 10-13, 15, 17-20, 23, 30, 33 and 35. Excluding discordant ages, the metamorphic ages can be grouped into the following sets: $2082.7 \pm 40.31\text{Ma}$ (1 analysis, Spot No.17); $1743.2 \pm 38.21\text{Ma}$ (1 analysis, Spot No.35); $957.6 \pm 15.21\text{Ma}$ (1 analysis, Spot No.03); $845.6 \sim 817.8\text{Ma}$ (2 analyses, Spot No.10,13); $646.3 \pm 6.74\text{Ma}$ (1 analysis,

Spot No.11); 434.5~420.7Ma (3 analyses, Spot No.04,12,23); 405.3±5.03Ma (1 analysis, Spot No.18).

Figure E10 CL images and the REE pattern of ST1513.

The concordant magmatic ages fall into the following groups: 2485.3~2484.8Ma (2 analyses, Spot No.01, 16); 970.4~940.1Ma (2 analyses, Spot No.06, 09); 443.1±7.34Ma (1 analysis, Spot No.26); 425.6~403.3Ma (6 analyses, Spot No.08, 21, 22, 24, 25, 32).

ST1512 and ST1513 are two samples from a granitoid body. The weighted mean average magmatic ages of youngest groups in ST1512 and ST1513 are 424.9 ± 2.2 Ma and 417 ± 11 Ma, respectively (Fig.E11). The formation of this granitoid body corresponds to the early Paleozoic granitoids in the north Qinling belt.

Figure E11 Concordia diagrams and weighted mean ages of TS1512 and TS1513, respectively.

3. Results from the Xinyang area

(1) XY1605

Zircons in XY1605 vary in size, and the size ranges from $20\mu\text{m}$ to $150\mu\text{m}$ (Fig.E12a). Some grains are subhedral and euhedral prismatic (e.g., Spot No.07, 08,

10, 11, 15), and some are equant forms (e.g., Spot No.23, 26, 27, 28), and some are fragments (e.g., Spot No.04, 20, 25, 37). Some zircons show igneous zoning (e.g., Spot No.01, 10, 11, 12), and others show blurred zoning or no zoning (Spot No.06, 17-19, 30, 32, 34, 35, 38-42, 44-46, 48, 51-54).

Th/U ratios are between 5.37 and 0.03. Spot No.32, 42, 51, 52 have Th/U ratios < 0.1 .

Spot No.02, 32, 34, 42, 46, 48, 50, 52 show abnormal patterns. Spot No.02, 34, 50 are abundant in LREE, and Spot No.32, 42, 46, 52 are depleted in HREE, and Spot No.48 shows a positive Eu-anomaly instead of a negative one (Figs.E12b,c).

In summary, metamorphic ages are Spot No.02, 06, 17-19, 30, 32, 34, 35, 38-42, 44-46, 48, 50-54. The concordant ages fall into several groups: 2185.1 ± 36.45 Ma (1 analysis, Spot No.44); 1952.7 ± 50.07 Ma (1 analysis, Spot No.19); 1148.3 ± 12.49 Ma (1 analysis, Spot No.41); $997.1 \sim 888.8$ Ma (4 analyses, Spot No.17, 30, 35, 45); $509.8 \sim 504.7$ Ma (3 analyses, Spot No.48, 51, 52); $499.2 \sim 484.7$ Ma (4 analyses, Spot No.32, 39, 40, 42); 455.1 ± 5.59 Ma (1 analysis, Spot No.38); 439.3 ± 6.05 Ma (1 analysis, Spot Mo.53).

The concordant magmatic ages can be divided into the following groups:
 $1769.8 \pm 39.99\text{Ma}$ (1 analysis, Spot No.24); 1501.9Ma (1 analysis, Spot No.05);
 $1089.8 \sim 1002$ (3 analyses, Spot No.01, 07, 14); $999.5 \sim 882.6\text{Ma}$ (3 analyses, Spot
No.04, 29, 49); $844.9 \sim 604.1$ (3 analyses, Spot No.16, 25, 26); $490.3 \pm 7.03\text{Ma}$ (1
analysis, Spot No.47); $467.1 \sim 462.8$ (2 analyses, Spot No.55, 56); $451 \sim 447.6\text{Ma}$ (3

Figure E12 CL images and the REE patterns of XY1605.

analyses, Spot No.13, 21, 22); 441.6 ± 4.02 Ma (1 analysis, Spot No.23); 423.3 ± 4.89 Ma (1 analysis, Spot No.33); $408.1 \sim 405.5$ (2 analyses, Spot No.31, 37); 374.6 ± 4.7 Ma (1 analysis, Spot No.03); 357.9 ± 4.53 Ma (1 analysis, Spot No.37); 234.5 ± 2.98 Ma (1 analysis, Spot No.15); 212.5 ± 2.12 Ma (1 analysis, Spot No.11); 201.8 ± 2 Ma (1 analysis, Spot No.10). The youngest age may indicate the crystallization age of this dyke (i.e., 201.8 ± 2 Ma).

(2) XY1601A

The shape and size of zircon grains in XY1601A are variable (Fig.E13a). The size ranges from 20 μ m to 150 μ m. Some are subhedral and euhedral prismatic in shape with variable length-to-width ratios. For example, Spot No.17 is needle-shaped, while Spot No.01 is equant, and Spot No.22 lies in the middle. Some are fragments (e.g., Spot No.05, 06, 11). There is no well-developed oscillatory zoning in these grains. Spot No.01, 07, 18 show weak zoning, and others show blurred zoning or homogenous domain.

Th/U ratios are between 1.71 and 0.01. Spot No.01, 10, 28 and 31 have Th/U ratios < 0.1.

Spot No.01, 04, 08, 10, 17, 20, 26 and 31 display abnormal REE patterns. Spot No.08, 17 are abundant in LREE, while Spot No.01, 04, 20, 26 are depleted in HREE, and Spot No.10 does not show positive Ce-anomaly and negative Eu-anomaly, and Spot No.31 does not show positive Ce-anomaly (Figs.E13b,c).

The concordant metamorphic ages can be divided into the following groups: 865.4 \pm 9.39Ma (1 analysis, Spot No.03); 1624.4~1412.5Ma (3 analyses, Spot No.15, 16, 22); 524.3~520.2Ma (2 analyses, Spot No.06, 20); 503.3~479Ma (4 analyses, Spot No.05, 24, 27, 30); 471.2~470.4Ma (3 analyses, Spot No.11, 19, 21); 454.4~453.9Ma (2 analyses, Spot No.10, 32); 432.8 \pm 5.96Ma (1 analysis, Spot No.09); 344.3 \pm 5.77Ma

Figure E13 CL images and the REE patterns of XY1601A.

(1 analysis, Spot No.25); 228.8 ± 2.9 Ma (1 analysis, Spot No.12). There is only one concordant magmatic age: 470.8 ± 5.2 Ma (Spot No.18). This age is probably a xenocrystic age.

(3) XY1601B

Zircons from XY1601B range from 40 μ m to 130 μ m in size (Fig.E14a). Some are prismatic (e.g., Spot No.09, 11), and some are equant (e.g., Spot No.02, 04). Only Spot No.03 shows weak zoning, and others show blurred zoning or homogenous domain.

Th/U ratios are between 0.08 and 0.79. Spot No. 04 has Th/U ratio (≈ 0.08) < 0.1.

Most of REE patterns show positive Ce-anomalies, negative Eu-anomalies and steeply slopes from LREE to HREE (Fig.E14b). Spot No.06, 07, 16 show different patterns. Spot No.06&07 are depleted in HREE and do not show positive Ce-anomaly, and Spot No.16 is depleted in HREE, and do not show positive Ce-anomaly and negative Eu-anomaly (Fig.E14c).

In summary, the concordant metamorphic ages can be divided into the following groups: 1025.8 \pm 12.39Ma (1 analysis, Spot No.11); 966.8~879.3Ma (6 analyses, Spot No.02, 08, 10, 13, 14, 15); 801.2 \pm 8.65Ma (1 analysis, Spot No.12); 716.2 \pm 8.15Ma (1 analysis, Spot No.04); 121.7 \pm 1.54Ma (1 analysis, Spot No.18).

Figure E14 CL images and the REE patterns of XY1601B.

There is only one concordant magmatic age: 859 ± 13.38 Ma (Spot No.03). This is a xenocrystic age.

(4) XY1602

The size of zircons in XY1602 is in the range of 40~140 μ m (Fig.E15a). Some are prismatic (e.g., Spot No.14, 24), and some are equant (e.g., Spot No.05, 17, 19), and some are ellipsoidal (e.g., Spot No.03, 18, 22). Some spots show weak zoning (Spot No.01, 02, 14, 15), and others show blurred zoning or homogenous domain.

Th/U ratios are in the range of 0.02~0.95. Spot No.07, 09, 19, 23 and 24 have Th/U ratios < 0.1.

Most of REE patterns show positive Ce-anomalies, negative Eu-anomalies and steeply slopes from LREE to HREE (Fig.E15b). Spot No.04, 06, 19, 23, 24 show different patterns. Instead of a negative Eu-anomaly, Spot No.23 and 24 show positive Eu-anomalies. Spot No.19 is relatively depleted in HREE, while Spot No.04, 06 and 24 are relatively abundant in LREE (Fig.E15c).

The metamorphic concordant ages can be divided into the following groups: 2365 \pm 23.76Ma (1 analysis, Spot No.12); 1458.4~1408.8Ma (4 analyses, Spot No.09, 10, 13, 20); 1247.1~1203.5Ma (2 analyses, Spot No.03, 08); 1082.3~1000.9Ma (2 analyses, Spot No.17, 18); 920.3 \pm 10.03Ma (1 analysis, Spot No.16); 792.1 \pm 9.12Ma (1 analysis, Spot No.05); 491.5 \pm 5.54Ma (1 analysis, Spot No.19); 447.9 \pm 5.86Ma (1 analysis, Spot No.21); 354.3 \pm 4Ma (1 analysis, Spot No.24).

There are only two concordant magmatic ages: 1462.8 \pm 18.8Ma (Spot No.15) and 1131.9 \pm 12.57Ma (Spot No.14).

Curriculum Vitae

Name: Mengmeng Qu

Education Background:

- **01/2014 ~ 06/2018:** PhD Student, Department of Earth Sciences, Western University
- **09/2012 ~ 12/2013:** MSc Student (upgrade to Ph.D. program), Department of Earth Sciences, Western University
- **09/2008 ~ 07/2012:** BSc, Department of Geology, Northwest University, Xi'an, China

Work Experience:

- **01/2018 ~ 04/2018, 05/2016 ~ 08/2016, 05/2015 ~ 08/2015, 05/2014 ~ 08/2014, 05/2013 ~ 08/2013:**
Research assistant at Laboratory for Structural Geology & Tectonics, Department of Earth Sciences, Western University
- **01/2016 ~ 04/2016:**
Instructor of Structural Geology, Department of Earth Sciences, Western University
- **09/2016 ~ 04/2017, 09/2015 ~ 12/2015, 09/2014 ~ 04/2015, 09/2013 ~ 04/2014, 09/2012 ~ 04/2013:**
Teaching assistant for the different courses in the Earth Sciences, Department of Earth Sciences, Western University
